Abstract

Current strategies for the synthesis of molecular knots focus on twisting, folding and/or threading molecular building blocks. Here we report that Zn(II) or Fe(II) ions can be used to weave ligand strands to form a woven 3×3 molecular grid. We find that the process requires tetrafluoroborate anions to template the assembly of the interwoven grid by binding within the square cavities formed between the metal-coordinated criss-crossed ligands. The strand ends of the grid can subsequently be joined through within-grid alkene metathesis reactions to form a topologically-trivial macrocycle (unknot), a doubly-interlocked [2]catenane (Solomon link) and a knot with seven crossings in a 258-atom-long closed loop. This 7₄ knot topology corresponds to that of the endless knot, which is a basic motif of Celtic interlace, the smallest Chinese knot and one of the eight auspicious symbols of Buddhism and Hinduism. The weaving of molecular strands within a discrete layer by anion template, metal ion coordination opens the way for the synthesis of other molecular knot topologies and to woven polymer materials.

Knots are fundamental elements of structure, exploited in basic tools and materials from shoelaces to fishing nets and woven fabrics.¹ At the molecular level, knots² form spontaneously in flexible polymer chains³ and are found in DNA and ~1 % of proteins in the protein data bank (PDB)⁴. Molecular level knotting influences properties such as elasticity,⁵ tensile strength⁵ and the expression of chirality,⁶ has been implicated in biological activity,^{4,7} and can assist the formation of precisely structured sites for binding^{8,9} and catalysis^{10,11}. Artificial molecular knots have been synthesised, sometimes unexpectedly, through the use of metal ion templates,¹²⁻²⁰ covalent scaffolds,²¹ hydrogen bonding,^{22,23} coordination bonds²⁴⁻²⁶ and/or hydrophobic-driven folding²⁷⁻²⁹ to direct their assembly³⁰⁻³². One of the most versatile routes to different molecular knots and links is based on cyclic helicate scaffolds,³¹ which twist two or three molecular threads about one another to generate strand crossings.

Simulations have identified 'privileged topologies' that are particularly accessible through such processes.³³ However, such self-assembly approaches are currently limited to a few simple or torus knots and certain classes of composite knots. Here we report on the synthesis of a seven-crossing (7₄ in Alexander-Briggs notation³⁴) molecular knot (Fig. 1).³⁵ It does not correspond to a previously identified privileged topology because it is prepared by a fundamentally different synthetic strategy: the use of metal ions to weave—rather than twist, fold or thread through a loop—molecular strands. A key intermediate in the formation of the knot is an interwoven 3×3 molecular grid, whose assembly depends on a specific anion to act as a template. Metal-ion coordination-driven two-dimensional weaving offers a route to new types of molecular knot topologies and woven molecular fabrics.

Molecular grids that consist of stacked layers^{36,37} of criss-crossed metal-coordinated ligands have attracted attention as potential information storage materials. In contrast, molecular grids featuring interwoven (rather than stacked) ligand strands are unknown, other than the simplest, 2x2, arrangement, which does not have internal crossings. Reasons for the scarcity of such molecular

architectures may be related to the consequences of strand rigidity: weaving requires more than just strands to cross one another; to create a mechanical entanglement every thread must pass over (at least) one thread, then under a subsequent one (or more), and then back over a third, returning to the original plane. In the macroscopic world wooden sticks can be woven into structures held together only by the pressure exerted between the sticks at the crossing points, but for a supramolecular assembly such stresses impose limitations and tolerances on metal-donor distances and geometries for internal coordination sites. We identified a strand design based upon thiazolo[5,4-d]thiazole (TTZ) units that we thought could minimize such strain. The TTZ moiety induces a zig-zag metal-ligand coordination motif where the metal centres align warp and weft ligand strands in an over-under pattern, the first part of a weave sequence. We previously used this basic unit for the synthesis of a Solomon link (a doubly-interlocked [2]catenane or 4²₁ link) and a granny composite knot from 2×2 grids featuring strictly coplanar metal ions.^{38,39} Extending this motif to complete the weave (i.e., forming an over-under-over sequence) might be possible without imposing significant strain if the additional third (internal) coordination site of each ligand strand held the extra metal ions within the same plane as the others in the grid.

Results and discussion

We explored a number of designs based on this concept, varying the coordination environment (e.g. shape, geometry, bond lengths, angles, spacers, and electron donating ability of the donor atoms) of the internal and outer binding sites of each strand. In every case the new ligands could be coordinated to metal ions (our binding experiments typically used zinc(II) triflate (Zn(OTf)₂) in non-coordinating solvents, which worked well with our previous 2×2 grid-forming ligands), but none formed in a stoichiometry consistent with a 3×3 grid. Most of the designs appeared to bind metal ions only in the outer coordination sites of each strand (see Supplementary Information section 2.1 for a discussion of the evolution of the ligand design).

One strand design, **1**, featured a TTZ group combined with a benzimidazole and pyridine unit for the two outer coordination sites and two TTZ motifs in combination with a 4-dimethylaminopyridine group at the inner site (Fig. 1). We envisaged that the electron donating ability of the 4-dimethylamino moiety should enhance the metal-ion-coordinating efficacy at this position, potentially sufficiently to overcome the stringent fit requirements necessary for the internal binding site. In preliminary coordination experiments of **1** with Zn(OTf)₂ in acetonitrile and chloroform, a complex mixture of products formed, with ¹H nuclear magnetic resonance (NMR) spectroscopy and mass spectrometric evidence for the formation of various sized metal-coordinated oligomers and a square coordination complex (the outer framework of the grid). Recalling that the X-ray crystal structure of the Solomon link assembled from TTZ-based ligands had a well-ordered BF₄⁻ anion positioned in the square cavity of the 2×2 grid,³⁸ one of us (J.-F.L.) decided to repeat the coordination-driven assembly of **1** replacing Zn(OTf)₂ with Zn(BF₄)₂. Remarkably, addition of 1.5 equivalents of Zn(BF₄)₂·6H₂O to **1** in chloroform/acetonitrile (1:1) led to the quantitative formation of a distinct coordination complex within 5 minutes, shown by Diffusion-Ordered ¹H NMR Spectroscopy (DOSY) to be a single species with a self-diffusion constant, *D*, of 2.9 × 10⁻⁶ cm²s⁻¹, confirmed by mass spectrometry to have the formula [Zn₉**1**₆](BF₄)₁₈. The ¹H NMR spectrum of [Zn₉**1**₆](BF₄)₁₈ in CD₃CN:CDCl₃ (1:1) at 298 K (Fig. 2b) reveals it to have a highly symmetrical structure, with the six ligands of **1** occupying two different environments in a 2:1 ratio. This is consistent with a 3×3 interwoven grid (*D*_{2d} symmetry) in which the four ligand strands of the exterior square are all chemically equivalent to each other, but are in a different environment to the two strands that make up the internal cross (which are also in mutually identical environments).

Fig. 2 | ¹H NMR spectra (600 MHz [except (f)], 298 K [except (f)]) of building block 1, metal-coordinated intermediate [Zn₉1₆](BF₄)₁₈, and ring-closed products 2-4. Note the broadening of the room temperature spectra (from (a) to (c) to (d) to (e)) as the structural complexity increases concomitantly with the time taken for each proton to sample the different environments available to it. (a) Ligand 1 in CDCl₃; (b) 3×3 interwoven grid [Zn₉1₆](BF₄)₁₈ in CD₃CN:CDCl₃ (1:1) (the grid is only sparingly soluble in pure CDCl₃); (c) macrocycle 3 in CDCl₃; (d) Solomon link 4 in CDCl₃; (e) 7₄ knot 2 in CDCl₃ at 298 K; (f) 7₄ knot 2 in C₂D₂Cl₄ at 393 K (500 MHz[§]). The lettering corresponds to the proton labelling in Fig. 1. For full spectral assignments see SI section 1.3-1.6. [§] 393 K is outside the temperature range of our 600 MHz NMR probe.

The analogous Fe(II) interwoven 3×3 grid, [Fe₉1₆](BF₄)₁₈, could be assembled from 1 and Fe(BF₄)₂·6H₂O, but its formation required prolonged heating at 100 °C. In both cases the use of tetrafluoroborate anions was crucial: interwoven grids did not form using a range of other Zn(II) and Fe(II) salts.

Variable temperature (VT) ¹H NMR in C₂D₂Cl₄ showed interwoven grid [Zn₉1₆](BF₄)₁₈ to be stable up to at least 100 °C. However, the grid could be spontaneously disassembled at room temperature by the addition of *N,N*-diisopropylethylamine, a relatively modest competitive ligand for Zn(II). The ¹H NMR spectrum of [Fe₉1₆](BF₄)₁₈ in CD₃CN displays significant broadening of several sets of signals, indicative of the presence of some paramagnetic high spin Fe(II) ions. Electrospray ionization mass spectrometry (ESI-MS) of [Fe₉1₆](BF₄)₁₈ and [Zn₉1₆](BF₄)₁₈ generated a series of multiply-charged ions, {[M₉1₆](BF₄)_n}⁽¹⁸⁻ⁿ⁾⁺ (M = Fe or Zn, n = 4–8), corresponding to the grid minus various numbers of BF₄⁻ anions (SI sections 1.4 and 1.5).

Single crystals of [Fe₉1₆](BF₄)₁₈ suitable for structure determination by X-ray crystallography were obtained by slow diffusion of toluene into a solution of the grid in acetone. The X-ray structure of [Fe₉1₆](BF₄)₁₈ (SI section 1.8) forms the grid of the modelled 7₄ knot structure shown in Fig. 3, in which the disordered alkene-terminated chains are replaced by Merck Molecular Force Field (MMFF)-modelled cyclized end groups. The X-ray structure confirmed the architecture as a 3×3 grid with each of the six ligands woven alternatively over or under another at nine co-planar Fe(II) ion crossing points. Four well-ordered BF₄⁻ anions are located in the square cavities formed between the weft and warp strands. The B-F bonds of the BF₄⁻ anions point in the direction of the metal ions at the corners of the square with the fluorine atoms in close contact with the centres of the thiazole rings (Fig. 3d), stabilizing

the assembly through a combination of charge-dipole and anion- π interactions.⁴⁰ The extended layered crystal structure of [Fe₉1₆](BF₄)₁₈ suggests a route to 2D woven molecular fabrics.⁴¹

The design of **1** is such that the alkene-terminated chains are sufficiently short that only adjacent strand ends on the 3×3 grid can reach each other to react through alkene metathesis, yet sufficiently long that conformations are available that avoid strain within the folded chains that could inhibit ring closure. Treatment of a dilute solution (2 mM) of [Zn₉1₆](BF₄)₁₈ in CH₂Cl₂/CH₃NO₂ 3:1 with the 2nd Generation Hoveyda–Grubbs catalyst⁴² (0.1 eq. per alkene) at 110 °C under microwave irradiation for 1 h followed by demetallation with Li₂S gave a product mixture that ESI-MS (Supplementary Fig. 30) showed consisted largely of closed-loop species derived from two, four or six molecules of **1** (SI section 2.3). The three major closed-loop species were separated by gel permeation chromatography from linear oligomers bearing unreacted alkene end groups (12 % of alkenes present in the product mixture after metathesis were terminal; SI section 1.6). Longer reaction times did not lead to significant changes in the product distribution, until thermal degradation started to decrease the overall yield of isolable material.

The second most abundant species (37 % of the demetallated product mixture) was found to be the smallest cyclic product, macrocycle **3**, derived from two molecules of **1**. The ¹H NMR spectrum of **3** (Fig. 2c) is similar to that of the original building block, **1** (Fig. 2a), other than the absence of the H_{a/a'} terminal alkene resonances and modest shielding of several protons (e.g. H_r and H_s) due to aromatic stacking. As expected for an unknot macrocycle with no asymmetrical features, chiral high performance liquid chromatography (chiral HPLC) showed no evidence for **3** being chiral.

The most abundant product **4**, which makes up 56 % of the demetallated product mixture, was shown by mass spectrometry to have a molecular mass corresponding to a closed-loop species derived from four molecules of **1**. The fragmentation pattern of the molecular ion (dethreading to half the mass once one macrocycle is broken open) and tandem mass spectrometry (Supplementary Fig. 13) indicated that **4** is a link (i.e., a catenane) made up of two interlocked molecules of **3**. Chiral HPLC showed **4** to be a racemic mixture of enantiomers (Supplementary Fig. 15), despite the building blocks having no elements of Euclidean chirality (centres, axes, helices, etc.). At 298 K the ¹H NMR spectrum of **4** (Fig. 2d) is broader than that of **3** (Fig. 2c), but sharpens at higher temperatures (e.g. Spectrum 20), characteristic of the temperature-dependent behaviour of interlocked rings rotating about one another. The diastereotopic splitting of methylene group H_k confirms the chirality of **4**. Given the absence of other features that can impart chirality, molecular link **4** cannot be the singly-interlocked (Hopf) link, which is topologically achiral, but rather must be the topoisomeric inherently chiral doubly-interlocked (Solomon) link.³⁸

Fig. 3 | Structure of 7_4 knot coordination complex $[\text{Fe}_9\mathbf{2}](\text{BF}_4)_{18}$, based on the X-ray crystal structure of $[\text{Fe}_9\mathbf{1}_6](\text{BF}_4)_{18}$ for the 3x3 grid region with MMFF-modelled cyclized end groups. (a) Viewed orthogonally to the plane of the nine Fe(II) ions. (b) Angled view showing the planarity of the weft and warp strands and the directionality of the anion $\cdots\pi$ and anion-Fe(II) interactions of the BF_4^- templates. (c) Viewed along the plane of the Fe(II) ions. (d) One of the square cavities formed between the criss-crossed strands in the X-ray crystal structure of $[\text{Fe}_9\mathbf{1}_6](\text{BF}_4)_{18}$, showing the B-F bonds pointing in the direction of the metal ions and close anion $\cdots\pi$ contacts between the fluorine atoms and the centres of thiazole rings: $\text{F}_3\text{B-F}\cdots\text{centroid}$ distances 2.88–3.23 Å. Carbon atoms are coloured light grey or turquoise. Nitrogen atoms are blue; iron, purple; oxygen, red; boron, pink; fluorine, green; sulfur, yellow. Other anions, the isopentyl chains and hydrogen atoms not shown for clarity.

The highest molecular mass product isolated forms 7 % of the demetallated mixture of cyclic products and was shown by mass spectrometry to have a molecular mass corresponding to a closed-loop species derived from six molecules of **1**. Remetallation of this material with $\text{Zn}(\text{BF}_4)_2 \cdot 6\text{H}_2\text{O}$ in $\text{CHCl}_3:\text{CH}_3\text{CN}$ (1:1) formed $[\text{Zn}_9\mathbf{2}](\text{BF}_4)_{18}$ (see Supplementary Fig. 18). The ^1H NMR spectrum of $[\text{Zn}_9\mathbf{2}](\text{BF}_4)_{18}$ (SI section 1.7) is related to that of the parent 3x3 grid $[\text{Zn}_9\mathbf{1}_6](\text{BF}_4)_{18}$, but is broader, lacks the terminal alkene protons, and the proton environments are less well resolved. The open 3x3 grid has D_{2d} symmetry but joining adjacent strands on the grid to form the metal-coordinated 7_4 knot forms two nugatory crossings² that changes the number of different chain environments. The ^1H NMR spectrum of the demetallated 7_4 knot, **2**, at room temperature in CDCl_3 is extremely broad (Fig. 2e). However, at 393 K in $\text{C}_2\text{D}_2\text{Cl}_4$ the signals sharpen significantly and become well resolved (Fig. 2f), with each distinct type of proton ($\text{H}_{b,j,l,r}$) giving rise to a single set of signals (the nugatory crossings only persist in the presence of metal ions), a feature characteristic of fast reptation⁴³ of the 258-atom-long knotted chain on the NMR timescale at this elevated temperature. Like Solomon links, 7_4 knots are topologically chiral, leading to diastereotopic H_k protons in **2** (Fig. 2f). However, **2** was insufficiently soluble in suitable solvents for separation of the enantiomers by chiral HPLC.

The presence (and the amounts formed) of different cyclized products from the 3x3 grid can be rationalized from consideration of the mechanism of formation of the 7_4 knot (Fig. 4; SI section 2.3). Although alkene metathesis can be under thermodynamic control in certain circumstances,⁴⁴ under the

conditions used here each joining reaction is essentially irreversible. Two different types of intra-complex olefin metathesis reactions occur on the grid: one connects strand ends at a corner of the grid ('corner join'); the other type connects the ends of two adjacent strands along a grid edge ('edge join'). Molecular modelling (Fig. 3) shows that the corner joins are more strained than the edge joins leading to reactions that connect strand ends along edges proceeding more rapidly than corner-forming connections. Under the high dilutions employed inter-grid reactions are rare; there was no evidence for grid dimers forming under these conditions by mass spectrometry.

Once one edge join is formed (shown on the 'north side' of the grid in intermediate **I**; Fig. 4), then alkene metathesis between adjacent strand ends on the opposite side of the grid can occur in two inequivalent ways (to form isomers **IIA** or **IIB**). If further edge joins on the east-west sides of **IIA** occur with the regiochemistry shown for **IIIA**, then the four remaining strand ends can form two corner joins leading to the 7_4 knot. However, if any of the edge joins occur with a different relative regiochemistry to **IIIA** then some strand ends are left without an adjacent partner with which to form a corner join and the 7_4 knot cannot form. If strand connections on one side of the grid do not affect the regiochemistry of alkene metathesis on another side then the maximum theoretical yield of the 7_4 knot is 12.5 %. Experimentally, we isolated **2** as 7 % of the mixture of closed-loop products. Exposure of the product mixture from grid alkene metathesis to fresh catalyst at different concentrations did not change the product distribution. If the products were in dynamic exchange, the yield of 7_4 knot could potentially increase as only its formation liberates the maximum number (six) of ethene molecules from intra-grid reactions.

The only other cyclic products that can result from intra-grid olefin metathesis are macrocycle **3** and Solomon link **4**. These were isolated experimentally as 37 and 56 %, respectively, of the closed-loop products. Without the ability to re-open incorrectly formed connections between adjacent strands on the grid, neither **3** nor **4** can act as intermediates to a 7_4 knot. Note that a Hopf link topology cannot arise from edge and corner joins on the interwoven 3×3 grid, nor can an unknot macrocycle or five-crossing Whitehead link be formed from connections between all six ligands on the grid.

Fig. 4 | Mechanism of formation of unknot macrocycle 3, Solomon link 4 and 7₄ knot 2 by connecting strand ends within a 3×3 interwoven grid, $[M_9 16](BF_4)_{18}$ ($M = Zn(II), Fe(II)$). If edge joins form more rapidly (and under kinetic control) than corner joins, and strand connections on one side of the grid do not affect the regiochemistry of connections on another side, then the maximum theoretical yield of the 7₄ knot is 12.5 % (SI section 2.3).

Conclusions

Originally unanticipated anion template interactions enable the quantitative, metal-ion-coordination driven, weaving of six ligand strands within a discrete molecular layer. Intra-grid closure of the chain ends of the resulting 3×3 interwoven grid can be used to generate a 7₄ knot, with kinetically controlled connections producing an unknot macrocycle and Solomon link as byproducts of the two-step assembly process. Fundamental elements of topology have previously been targeted to exemplify new strategies in synthesis, including the first examples of small-molecule Borromean rings,⁴⁵ pentafoil knots¹⁵ and a Star of David catenane⁴⁶. The 7₄ knot is a basic motif of Celtic knotting, the smallest Chinese knot, and is one of the eight auspicious symbols (the Ashtamangala) common to many Eastern religions and philosophies, where it represents the union of wisdom and method. The practical significance of its preparation in molecular form include the lessons learnt from its assembly (ligand design, metal and anion template weaving, mechanism of end-joining, etc.), which open the way for the bottom-up, coordination-driven assembly of polymer chains woven in two-dimensions⁴⁷⁻⁵¹ and other knotted and entangled molecules and materials.

Acknowledgements

We thank Jonathon E. Beves (now University of New South Wales) for early ligand designs for this project; the Engineering and Physical Sciences Research Council (EPSRC; EP/P027067/1), the European Research Council (ERC; Advanced Grant No. 786630), the China 1000 Talents Plan and East China Normal University for funding; the EPSRC National Mass Spectrometry Service Centre (Swansea, UK) for high-resolution mass spectrometry; the Diamond Light Source (UK) for synchrotron beam time on I19 (XR029); networking contributions from the COST Action CA17139, EUTOPIA; and Alberto Valero for the video of the rotating 7₄ knot structure. D.A.L. is a Royal Society Research Professor.

Author Contributions

J.J.D., S.D.P.F., J.F.L. and S.L.W. carried out the synthesis and characterization studies. G.F.S.W. solved the crystal structure. D.A.L. directed the research. All authors contributed to the analysis of the results and the writing of the manuscript.

Competing Interests Statement

The authors declare no competing interests.

Methods

Synthesis of endless knot **2**, Solomon link **4** and macrocycle **3** by olefin metathesis and demetallation of 3×3 interwoven grid

[Zn₉**1**]₆(BF₄)₁₈ (360 mg, 40 μmol) or [Fe₉**1**]₆(BF₄)₁₈ (360 mg, 40 μmol) and Hoveyda-Grubbs 2nd generation catalyst (30 mg, 48 μmol, 0.10 eq per free olefin) were added to a 20 mL microwave vial equipped with a magnetic stirrer. The vial was sealed and inerted *via* three cycles of vacuum/nitrogen purging. Dry and degassed (nitrogen bubbling) CH₂Cl₂ (15 mL) and CH₃NO₂ (5.0 mL) were added *via* syringe and the mixture sonicated until all solids had dissolved (approx. 30 seconds). The vial containing the reaction mixture was heated to 110 °C under microwave irradiation for 90 minutes (approx. 6.0 bar of pressure was generated within the vial over the course of the reaction). After the mixture was cooled to room temperature, ethyl vinyl ether (3.0 mL) was added. The mixture was stirred for 5.0 minutes and subsequently transferred to a round-bottom flask. The solvents were removed under reduced pressure and the residue dissolved in CH₃CN (5.0 mL). Diethyl ether (25 mL) was added to afford a yellow/brown precipitate, which was isolated by vacuum filtration over celite. The solid was washed with fresh diethyl ether (25 mL), and redissolved in CH₃CN (25 mL). CHCl₃ (25 mL) was added to the solution, followed by water (5.0 mL) and Li₂S (30 mg, 0.65 mmol) when using [Zn₉**1**]₆(BF₄)₁₈ or Na₄EDTA (380 mg, 1.0 mmol) when using [Fe₉**1**]₆(BF₄)₁₈. The mixture was stirred vigorously for 1.0 h, after which the mixture was partitioned between CHCl₃ (250 mL) and water (250 mL) and the organic phase separated. The aqueous phase was further extracted with CHCl₃ (3 × 100 mL) and the combined organics washed with brine (250 mL) and dried (Na₂SO₄) before concentrating to dryness under reduced pressure. The resulting orange solid was redissolved in CHCl₃ and passed over a plug of silica, eluting with CHCl₃/MeOH 9:1 until the liquors were colourless. Mass recovery of organic material with respect to input of ligand **1** was 140 mg after reconcentration, approximating to 50% when using either [Zn₉**1**]₆(BF₄)₁₈ or [Fe₉**1**]₆(BF₄)₁₈. The mixture was purified by a combination of recycling GPC (eluent CHCl₃/Et₃N 99.5:0.5) and preparative TLC (SiO₂, CH₂Cl₂/MeOH/Et₃N 92:7:1) to afford **2**, **4** and **3** as bright yellow powders in a 7:56:37 ratio.

Data Availability Statement

The data that support the findings of this study are available within the paper and its Supplementary Information, or are available from the Mendeley data repository (<https://data.mendeley.com/>) under doi:10.17632/g5b854f68w.1. CCDC-2022144 contains the supplementary crystallographic data. These data can be obtained free of charge *via* www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).
