Deformylation reaction by a nonheme manganese(III)-peroxo complex via initial hydrogen atom abstraction**

Abstract: Metal-peroxo intermediates are key species in the catalytic cycles of nonheme metalloenzymes, but their chemical properties and reactivity patterns are still poorly understood. We report here the synthesis and characterization of a manganese(III)-peroxo complex with a pentadentate bispidine ligand system and studied its reactivity with aldehydes. We show that manganese(III)-peroxo can react through hydrogen atom abstraction reactions instead of the commonly proposed nucleophilic addition reaction. Evidence of the mechanism comes from experiments which identify a primary kinetic isotope effect of 5.4 for the deformylation reaction. Computational modelling supports the established mechanism and identifies the origin of the reactivity preference of hydrogen atom abstraction over nucleophilic addition.

The chemistry of metal–dioxygen intermediates has attracted interest in the field of biological as well as bioinorganic chemistry communities for many decades. These complexes are key intermediates in the catalytic cycles of metalloenzymes that activate and utilize molecular oxygen for vital biological processes in the human body, including the metabolism of drugs and the biosynthesis of hormones.[1] Although many metalloenzymes use iron as the central cofactor, several actually use manganese instead. Biologically active manganese ions are included, for instance, in the oxygen-evolving complex of Photosystem II,[2] but also in superoxide dismutase that catalyzes the detoxification of superoxide and hydrogen peroxide to water.[3] The manganese-peroxo intermediate has been postulated as an important intermediate in these catalytic cycles; however, as it is short-lived, there currently is no experimental evidence available. Therefore, synthetic, biomimetic, models have been developed that have a ligand architecture suitable for studies in solution but have a coordination sphere that resembles enzyme analogues and consequently may give insight into the chemical and spectroscopic properties of enzymatic intermediates and their reactivity patterns.[4]

In the past few years several biomimetic metal-peroxo adducts of iron and manganese have been prepared and characterized with UV/Vis, electronic absorption, electron paramagnetic resonance (EPR) and X-ray absorption spectroscopic techniques.[5-8] In addition, reactivity patterns with model substrates were studied and showed these metal-peroxo species to mainly react through nucleophilic addition reactions.[9] Recently, a nonheme manganese(III)-peroxo complex with cyclam-type ligand was spectroscopically characterized with electronic absorption, EPR and X-ray absorption techniques. Moreover, the complex was shown to react with manganese(II)-chloride to form manganese(IV)-oxo and manganese(III)-hydroxo complexes.[9]

Scheme 1. Reactant complex [Mn^{II}(L')_2(O_2)]^+ and the possible reactivity patterns with 2-PPA substrate.

Synthetic metal-peroxo complexes are known to react with aldehydes efficiently in a proposed nucleophilic reaction mechanism. However, an alternative mechanism, not considered previously, concerns a rate determining hydrogen atom abstraction from the α-position prior to oxygen atom transfer. Recent work of metal-bispidine ligand systems showed...
these complexes to react efficiently with substrates through hydrogen atom abstraction, due to their rigid ligand framework, and reaction rates could be monitored effectively over a broad temperature and concentration range.\cite{10} Therefore, we decided to investigate the relative reactivity of the [Mn\textsuperscript{II}(L\textsuperscript{1})(O\textsubscript{2})\textsuperscript{2+}] complex, Scheme 1, with aldehydes and study the possible nucleophilic addition versus hydrogen atom abstraction mechanisms. In particular, we report the synthesis and characterization of a novel side-on manganese(III)-peroxo complex with a pentadentate bispidine N\textsuperscript{5} ligand, [Mn\textsuperscript{II}(L\textsuperscript{1})(O\textsubscript{2})\textsuperscript{2+}] (1).\cite{11} Scheme 1, and study its reactivity patterns with 2-phenylpropionaldehyde (2-PPA) and its \( \alpha \)-deuterated form. The starting manganese(II) complex, [Mn\textsuperscript{II}(L\textsuperscript{1})(ClO\textsubscript{4})\textsuperscript{2-} (2), was synthesized by reacting Mn\textsuperscript{III}(ClO\textsubscript{4})\textsubscript{2}·2MeCN with the pentadentate bispidine ligand (L\textsuperscript{1}) in CH\textsubscript{2}CN under an argon atmosphere in analogy to previously reported procedures.\cite{12} Addition of 10 equivalents of H\textsubscript{2}O\textsubscript{2} to a colorless solution containing [Mn\textsuperscript{II}(L\textsuperscript{1})(ClO\textsubscript{4})\textsuperscript{2-} (2; 2 mM) and triethylamine (TEA; 2.5 equivalents) in an acetonitrile solution at 15°C afforded a blue intermediate (1) with an absorption band at 605 nm (\( \varepsilon \) = 270 M\textsuperscript{-1} cm\textsuperscript{-1}; with a half-life ~60 minutes, Figure 1a, see the Supporting Information for experimental details). The blue intermediate is characterized with various spectroscopic techniques including UV-vis, high-resolution electrospray ionization-mass spectrometry (ESI-MS) and DFT. The ESI mass spectra of 1 exhibit a prominent ion peak with \( m/z \) 678.31 whose isotopic distribution pattern corresponds to [Mn\textsuperscript{II}(L\textsuperscript{1})(O\textsubscript{2})\textsuperscript{2+}] (Figure 1b). These spectra are similar to those found by Jackson et al. on an analogous manganese(III)-peroxo complex.\cite{9}

The nucleophilic and electrophilic character of 1 was then investigated in a reaction with 2-PPA as a substrate. Previous work showed that manganese(III)-peroxo complexes react with aldehydes to give the corresponding deformylated products by attacking the carbonyl group in a nucleophilic reaction.\cite{6c,6d} Upon addition of 2-PPA to 1 in CH\textsubscript{2}CN at 15°C, the intermediate decayed immediately and led to acetophenone as product. (Figure 2a). The pseudo-first-order rate constant of the decay of 1 increased linearly with increasing 2-PPA concentration, thus giving a second-order rate constant of \( 2.74 \times 10^{-2} \) M\textsuperscript{-1} s\textsuperscript{-1}.

The inset shows the time trace for the formation of 1. b) ESI-MS spectrum of 1. Inset shows the observed isotope distribution patterns for [Mn\textsuperscript{II}(L\textsuperscript{1})(O\textsubscript{2})\textsuperscript{2+}].

![Figure 2](image2.png)

**Figure 2.** Kinetics of the reaction of 1 with 2-PPA: a) UV/Vis spectral changes of 1 (2 mM) upon addition of 2-PPA (160 mM) in the presence of TEA (5 mM) and hydrogen peroxide (20 mM) in CH\textsubscript{2}CN at 15°C. Inset shows the time course of absorbance at 605 nm. b) Plot of \( k_{obs} \) against the concentration of 2-PPA and \( \alpha\text{-}[D\textsubscript{1}]\text{-PPA} \) (90%, D enriched) and the derived second-order rate constant for the reaction of 2 mM 1 with substrate at various concentrations in CH\textsubscript{2}CN at 15°C for 2-PPA (\( \bullet \)) and \( \alpha\text{-}[D\textsubscript{1}]\text{-PPA} \) (\( \ast \)). To establish whether the mechanism proceeds through a nucleophilic attack on the carbonyl group we used \( \alpha\text{-}\alpha\text{-dimethylbenzeneacetaldehyde} \) (2-Me-2-PPA) as a mechanistic probe. Upon addition of 2-Me-2-PPA to 1 at 15°C, the intermediate decays at the rate of its natural decay. However, when the reaction solutions were analyzed with ESI-MS no deformed products were observed. These results demonstrate that the manganese(III)-peroxo does not react with 2-PPA through a nucleophilic attack on the carbonyl group. As such, the work contradicts previous studies on the reactivity of nonheme and heme metal-peroxo complexes with aldehydes, that all reported a nucleophilic mechanism.\cite{10b,6a,13}

In order to find out, whether an alternative pathway was possible starting with an initial hydrogen atom abstraction, we decided to investigate the reaction with \( \alpha\text{-}[D\textsubscript{1}]\text{-PPA} \). Thus, upon addition of \( \alpha\text{-}[D\textsubscript{1}]\text{-PPA} \) (~90%, D enriched) to 1 in CH\textsubscript{2}CN at 15°C we determined a second-order rate constant of 5.05 \( \times \) 10\textsuperscript{-3} M\textsuperscript{-1} s\textsuperscript{-1} (Figure 2b). Therefore, our kinetics studies establish the manganese(III)-peroxo complex to react with 2-PPA via a rate determining hydrogen atom abstraction reaction from the \( \alpha \)-position with a kinetic isotope effect (KIE) of 5.4.

To further evidence of this novel reaction mechanism, we performed a radical trapping experiment with bromotrifluoromethane using procedures reported previously.\cite{14} Addition of 2-PPA to intermediate 1 in the presence of excess CCl\textsubscript{3}Br (or CBr\textsubscript{4}) in CH\textsubscript{2}CN at 15°C, leads to the formation of \( \alpha\text{-brominated} \) product of the 2-PPA exclusively, which was confirmed by NMR.
analysis (Supporting Information). Consequently, our kinetics and reactivity studies clearly reveal a novel reaction mechanism between manganese(III)-peroxo complexes with aldehydes starting from an α-hydrogen atom abstraction step.

To gain further insight into the rate determining step for the reaction of manganese(III)-peroxo with aldehydes, we decided to follow the experimental work up with a set of density functional theory calculations following previously reported procedures.[15] Two pathways were investigated, namely (i) hydrogen atom abstraction by 1 from the α-position of 2-PPA and (ii) nucleophilic attack of the peroxo group on the carbonyl moiety of 2-PPA. The optimized geometries of the hydrogen atom abstraction (5TS_{HA}) and nucleophilic transition state (5TS_{NA}) are given in Figures S15 and S18. Here, we will focus on the analysis of the results and the understanding as to why the hydrogen atom abstraction pathway is favorable. The hydrogen atom abstraction barrier is relatively central with close values of the C–H and H–O distances and as expected happens with a large imaginary frequency for the C–H–O stretch typical for hydrogen atom abstraction reactions.[16] In agreement with experimental observation the lowest barrier is 5TS_{HA} (ΔE+ZPE‡ = 23.9 kcal mol⁻¹). By contrast, the nucleophilic transition state (5TS_{NA}) is well higher in energy (ΔE+ZPE‡ = 28.7 kcal mol⁻¹).

To understand the mechanistic preference of hydrogen atom abstraction over nucleophilic addition, we devised a novel two-parabola curve crossing diagram to explain the reaction mechanism, which shows analogy to the valence bond curve crossing diagrams of Shaik.[17] Figure 3 shows details of the two-parabola curve crossing model. Thus, we consider the reaction along the reaction coordinate (x) that starts in the reactants (at x = 0) that via a reaction barrier is connected to another local minimum at x = 1. We assume that the potential energy curve (y) can be described with a parabola with function y_{R} = ax² for the reactant complex and y_{P} = bx² + cx + d for the products. If we assume that the transition state for the reaction happens at a reaction coordinate x = ½ then these two curves will cross at x = ½ and using the values for y_{R}(0), y_{R}(½), y_{R}(1) and y_{P}(1), we can derive an equation for the curve crossing energy (ΔE_{cross}) as a function of the Franck-Condon energy in the reactants (E_{FC,R}) and the driving force for the reaction (ΔE_{rp}), Eq 1, as defined in Figure 3.

\[
\Delta E_{cross} = \frac{1}{4} E_{FC,R} + \frac{3}{4} \Delta E_{rp} \tag{1}
\]

As shown previously using valence bond curve crossing diagrams,[17] the actual transition state is below the curve crossing energy by an amount B (the resonance energy), so that we can predict the value of the transition state based on estimates for E_{FC,R}, ΔE_{rp} and B, Eq 2.

Figure 3. Two-parabola curve crossing rationalization of the hydrogen atom abstraction pathway in the reaction of 1 with 2-PPA. Bond orbital changes along the pathways highlighted. Dots represent electrons and a line between two dots is a bond occupied by two electrons. Straight arrows indicate spin orbitals. Also shown is the VB representation of the alternative nucleophilic intermediate P_{NA}.
We then analyzed the bond breaking and orbital changes between reactants, transition states and intermediates for the rate determining reaction step to predict the Franck-Condon energy between \( ^1\text{R} \) and \( ^2\text{R} \) and give details in Figure 3 in a Valence Bond format. These VB schemes were used previously to predict reactivities and rationalize reactivity trends.\(^{18}\) Thus, the hydrogen atom abstraction is accomplished through the breaking of the \( \alpha\text{CH} \) bond of the substrate leading to atomic \( 2\text{p}_\text{C} \) and \( 1\text{s}_\text{H} \) orbitals, which energetically is equal to the bond dissociation energy of the \( \text{C}--\text{H} \) bond (\( \text{BDE}_{\text{OH}} \)). On the oxidant side of the reaction the \( \pi\text{DO}_{\text{OXY}} \) and \( \pi^*\text{DO}_{\text{OXY}} \) pair of orbitals revert back to atomic orbitals and will cost an energy \( \text{E}_{\text{O--O}} \). This will generate two doubly occupied \( 2\text{p} \) atomic orbitals, one on each oxygen atom. One of those \( 2\text{p} \) electrons on the terminal oxygen atom will form a bond with the incoming hydrogen atom, while the other electron is transferred to the \( 3\text{d}_\text{Mn} \) on Mn. Finally, the other \( 2\text{p} \) orbital on oxygen atom O1 will form a three-electron bond with the \( 3\text{d}_\text{Mn} \) on manganese and form the \( \pi\text{DO}_{\text{OXY}} \) and \( \pi^*\text{DO}_{\text{OXY}} \) pair of orbitals. The Franck-Condon energy, therefore, can be described as the sum of the BDEs, \( \text{E}_{\text{O--O}} \) and \( \text{E}_{\text{H}} \).

We calculate a BDE of \( 80.3 \text{ kcal mol}^{-1} \), which is in excellent agreement with the DFT barrier reported in the literature. Similarly to the hydrogen atom abstraction process the side substrate carbonyl involves a lower energy pathway than transferring an electron from peroxo to manganese and iron-peroxo complexes, such as the aldehyde deforming dioxygenases\(^{20}\) to find out whether this is a general mechanism.
