Abstract

Cosmic spherules collected from deep sea sediments of the Indian Ocean having different textures such as scoriaceous (4), relict-bearing (16), porphyritic (35) and barred olivine (2) were investigated for petrography, as well as high precision oxygen isotopic studies on olivine grains using secondary ion mass spectrometry (SIMS). The oxide FeO/MgO ratios of large olivines ($> 20\mu\text{m}$) in cosmic spherules have low values similar to those seen in the olivines of carbonaceous chondrite chondrules, rather than matching the compositions of matrix. The oxygen isotope compositions of olivines in cosmic spherules have a wide range of $\delta^{18}\text{O}$, $\delta^{17}\text{O}$ and $\Delta^{17}\text{O}$ values as follows: -9 to 40‰ , -13 to 22‰ and -11 to 6‰ . Our results suggest that the oxygen isotope compositions of the scoriaceous, relict-bearing, porphyritic and barred spherules show provenance related to the carbonaceous (CM, CV, CO and CR) chondrites. The different types of spherules that has experienced varied atmospheric heating during entry has not significantly altered the $\Delta^{17}\text{O}$ values. However, one of the relict-bearing spherules with a large relict grain has $\Delta^{17}\text{O} = 5.7\text{‰}$, suggesting that it is derived from ^{16}O -poor material that is not recognized in the meteorite record. A majority of the spherules have $\Delta^{17}\text{O}$ ranging from -4 to -2‰ , similar to values in chondrules from carbonaceous chondrites, signifying that chondrules of carbonaceous chondrites are the major contributors to the flux of micrometeorites, with an insignificant fraction derived from ordinary chondrites. Furthermore, barred spherule data shows that during atmospheric entry an increase in $\sim 10\text{‰}$ of $\delta^{18}\text{O}$ value surges $\Delta^{17}\text{O}$ value by $\sim 1\text{‰}$.

1. INTRODUCTION

The Earth is continuously bombarded by an extra-terrestrial material flux of ~30,000 tons per annum (Love and Brownlee, 1991). While more than 90% of this material gets evaporated in the atmosphere, a fraction of the colliding particles survive atmospheric entry heating to reach the Earth's surface (Taylor et al., 1998; Yada et al., 2004; Plane, 2012; Prasad et al., 2013). The survivability of these particles that penetrate the Earth's atmosphere depends on various factors such as mass, density, velocity, zenith angle during entry and chemical compositions that are markedly different for different precursors (Love and Brownlee, 1991, 1993; Rudraswami et al., 2015a). The micrometeorites that have entered Earth's atmosphere at high zenith angle and low velocity are interesting because their petrologic and isotopic characteristics are largely preserved thereby providing constraints on the parent body they have originated from. However, those micrometeorite particles that enter at low zenith angle and high velocity experience large heating and vaporization during entry, thereby altering the chemical and isotopic compositions. Under such circumstances, relating the chemical composition of the micrometeorites/cosmic spherules to their origins is marred by uncertainties (Kurat et al. 1994, Beckerling and Bischoff 1995, Brownlee et al. 1997, Greshake et al. 1998; Cordier et al., 2011; Rudraswami et al., 2012).

Oxygen isotope studies complemented by mineralogical compositions are vital to unravel the complexity involved in distinguishing the known components of micrometeorites and their parent bodies. For carbonaceous chondrites, the oxygen isotope compositions of the chondrules, CAIs and matrix fall close to the Carbonaceous Chondrite Anhydrous Minerals (CCAM) line with slope ~1 (Clayton et al., 1993). Mixing of these different components with nebular gas, and parent-body processing after accretion, led to changes in $\delta^{18}\text{O}$ and $\Delta^{17}\text{O}$ values (Yurimoto et al., 2008). However, the chondrules in ordinary chondrites have a

different trend than carbonaceous chondrites and fall above the CCAM line (Clayton et al., 1991; Kita et al., 2010). For cosmic spherules, interactions with the terrestrial atmosphere during atmospheric entry without substantial evaporative mass loss do not alter the $\Delta^{17}\text{O}$, but can change the $\delta^{18}\text{O}$ value significantly (Engrand et al., 2005; Suavet et al., 2010; Rudraswami et al., 2015b). Despite the effects of atmospheric mixing, some cosmic spherules retain relict grains that preserve their primary oxygen isotope signatures, indicating that they did not crystallize from a melt during atmospheric entry (Engrand et al., 2005; Yada et al., 2005; Genge et al., 2008; Suavet et al., 2010; Rudraswami et al., 2015b).

One of the issues we wish to address here is whether exchange of $\delta^{17,18}\text{O}$ between a micrometeorite and the atmosphere will preclude an understanding of its parent body. In an earlier study, we showed that most Mg-rich relict olivine grains of cosmic spherules have $\Delta^{17}\text{O}$ ranging from -5 to 0‰ , thereby suggesting that chondrules of carbonaceous chondrites could be the origin for the relict bearing cosmic spherules (Rudraswami et al., 2015b). In addition, some Mg-rich relict olivine grains are very ^{16}O -rich, with $\Delta^{17}\text{O}$ ranging from -21.9 to -18.7‰ , similar to oxygen isotopic compositions observed in calcium aluminium rich inclusions (CAIs), amoeboid olivine aggregates (AOAs), and some porphyritic chondrules from carbonaceous chondrites (Rudraswami et al., 2015b). Earlier studies were done on large sized relict bearing cosmic spherules largely dominated by forsteritic olivine. In the present study, we have performed high precision ion microprobe oxygen isotope analyses of olivines in 57 cosmic spherules having different textures (scoriaceous, relict-bearing, porphyritic and barred) that has experienced different heating (i.e. partially to large scale heating) during atmospheric entry. The objectives is to see the oxygen isotope variation in different type of cosmic spherules and compare with different chondrites and their components. This will benefit in recognizing and probably quantifying the range of contributors to the micrometeorite flux on the Earth. Secondly, the particle as it enter the stratosphere undergo

oxygen isotopic modification leading to enrichment of $\delta^{17,18}\text{O}$. Distinguishing the variations in $\delta^{17,18}\text{O}$ and $\Delta^{17}\text{O}$ will be beneficial to identify the parent bodies of these particles.

2. SAMPLE SELECTION

Cosmic spherules chosen for the present investigation were collected from the deep-sea sediments of the Indian Ocean from a seafloor depth of ~5000 m. A grab sampler of size 50×50 cm (length × breadth) has been used to sample the seafloor sediments: the sampler penetrates to a depth of ~15 cm and has the capacity to pick up ~ 45 kg of wet sediments (Rudraswami et al., 2011a; Rudraswami et al. 2012; Prasad et al., 2013). The sediments were sieved using a 200 μm mesh sized sieve and the >200 μm portions were dried and subjected to magnetic separation. Individual spherules were handpicked under a binocular microscope from these magnetic separates. A total of ~2500 spherules were mounted in 12 sections which were carefully ground and polished to expose the internal textures. Fifty seven cosmic spherules of different types, have experienced different stages of heating during entry and that have large olivine grain (>20 μm), were selected for oxygen isotope studies from the total ~2500 observed under scanning electron microscope (SEM). We focus on olivine oxygen isotope studies in different micrometeorites as a fairly robust indicator to understand precursor meteorite body, and different level of heating in different types of cosmic spherules will provide information on stratospheric oxygen isotope exchange during interaction. The selection criteria for spherules was to sample a representative selection of different petrographic textures and types such as scoriaceous (4), relict-bearing (16), porphyritic (35) and barred olivine (2).

3. ANALYTICAL TECHNIQUES

A JEOL JSM 5800LV SEM having an OXFORD INCA energy dispersive spectrometer detector (EDS, ISIS-300 at National Institute of Oceanography, Goa) was used to observe high resolution back scattered electron images (BSE) for classifying the spherules. The images were used to select the best spherules and identify phases for chemical and oxygen isotope analyses using electron microprobe and ion microprobe, respectively. A Cameca SX5 Electron Micro Probe Analyzer (EPMA at National Institute of Oceanography, Goa) equipped with four spectrometers was used to determine the elemental composition of different phases in the spherules, and the operating conditions are identical to those used in Rudraswami et al. (2015b). After SEM and EPMA analyses, we selected 57 cosmic spherules having olivines with grain sizes $>20\text{ }\mu\text{m}$ for further oxygen three isotope studies based on morphological features and the grain sizes.

Oxygen three isotope analyses on cosmic spherules were performed using the Secondary Ion Mass Spectrometer (SIMS, Cameca IMS 1280 at University of Hawaii, USA). The Cs^+ primary beam ion current $\sim 1\text{ nA}$ was rastered over $7 \times 7\text{ }\mu\text{m}$ on the selected phase for measuring secondary ions. The mass resolving power ($M/\Delta M$) used for $^{16}\text{O}^-$ and $^{18}\text{O}^-$ was ~ 2000 . Higher mass resolving power of ~ 5600 was used for $^{17}\text{O}^-$ to resolve the contribution of $^{16}\text{OH}^-$. The instrument mass fractionation was corrected using San Carlos olivine as the running standard. Analyses that deviated from the selected spots, and which overlap inclusions, cracks or grain boundaries, are excluded from the study. Detailed analytical conditions were similar to those used by Rudraswami et al. (2015b).

4. RESULTS

Representative BSE images of cosmic spherules studied for oxygen three isotope analyses using ion microprobe are shown in Fig. 1. Appendix A provides 57 BSE images of all the cosmic spherules studied for oxygen isotopic composition. Although many spherules contain large grains, the presence of relict grains in spherules is not very common. Relict minerals, as defined here, can be distinguished from secondary crystallized grains (minerals that crystallized rapidly subsequent to atmospheric melting) by their grain size, morphology, Mg-rich composition and/or presence of pure Fe,Ni-metal inclusions (Genge et al., 2008). The chemical compositions and the oxygen three isotope analyses of the olivine grains are provided in Appendix B and Table 1, respectively.

Four scoriaceous spherules namely, AAS62-61-P64, AAS62-9-P43, AAS62-9-P51 and AAS62-9-P54 were identified for oxygen isotope studies (Fig. 1a,b and Appendix A). These spherules contain rare relict grains which are Mg rich with Fo content ranging from ~98 to 99%, except in the case of AAS62-9-P54 which has low Fo content (Appendix B and Table 1). The spread in oxygen isotope compositions in the relict olivine grains from scoriaceous spherules is as follows: $\delta^{17}\text{O} \sim -12.4$ to 7.9‰ , $\delta^{18}\text{O} \sim -2.4$ to 19.4‰ and $\Delta^{17}\text{O} \sim -11.2$ to -2.2‰ (Fig. 2a and Table 1). Two olivine grains with Fo contents of ~99 and 49 in AAS62-9-P51 and AAS62-9-P54, respectively, fall close to CCAM (Carbonaceous Chondrite Anhydrous Mineral) line, while the one in AAS62-61-P64 is displaced to the right side of the CCAM line (Fig. 2a). The olivine grain in AAS62-9-P43 has an isotopic composition that is close to TF (Terrestrial Fractionation) line and approaching the stratospheric oxygen isotope composition of $\delta^{18}\text{O} = 23.5\text{‰}$, $\delta^{17}\text{O} = 11.8\text{‰}$ (Thiemens et al., 1995: Fig. 2a and Table 1).

Relict-bearing spherules have large size grains that are usually Mg-rich in a groundmass of small grains. Sixteen relict-bearing cosmic spherules were identified based on the presence of Mg-rich and large size grains (Figs. 1c,d and Appendix A, B). The relict grain bearing spherules have oxygen isotope compositions with $\delta^{17}\text{O}$, $\delta^{18}\text{O}$ and $\Delta^{17}\text{O}$ as follows:

173 -10.6 to 11.3‰ , -8.5 to 23.7‰ and -9.9 to 5.7‰ , respectively (Fig. 2b, Table 1). Four
 174 spherules, AAS38-169-P59, AAS38-203-P67, AAS62-51-P24 and AAS38-207-P42, have
 175 single grains that are much larger and visually dominate the whole spherule (Appendix A).
 176 The relict olivine grain in AAS38-169-P59 has an oxygen isotope composition that falls
 177 above the TF line, $\Delta^{17}\text{O} = 5.7 \text{‰}$ (Fig. 3a). AAS38-203-P67 contains several relict olivines
 178 (Appendix A) with similar forsterite contents ($\sim 99\%$) which contain small Fe–Ni inclusions.
 179 The oxygen isotope compositions of olivine grains in spherule AAS38-203-P67 are very
 180 uniform and mostly lie between the CCAM and TF line (Fig. 3b). AAS62-51-P24 (Appendix
 181 A) has a single large forsterite grain (Fo $\sim 95\%$) with homogeneous chemical composition
 182 except for a more FeO-rich overgrowth at the edge, which is the result of heating during
 183 atmospheric entry. Such spherules are rare and the oxygen isotope composition of this
 184 spherule, based on two analyses, seems to be uniform with $\Delta^{17}\text{O} \sim -0.4 \text{‰}$. The data fall on
 185 the TF line (Fig. 3c). The two analyses in the relict grain of AAS38-207-P42 fall on the
 186 CCAM line ($\Delta^{17}\text{O}$ is -2.8 and -3.3‰), with $\delta^{18}\text{O}$ of 1.9 and 2.1‰ , respectively, but one
 187 analysis closer to the boundary of the grain shows a high $\delta^{17,18}\text{O}$ value ($\delta^{18}\text{O} = 22\text{‰}$)
 188 although $\Delta^{17}\text{O}$ (-3.3‰) is identical to the other two analyses (Figs. 3d, Appendix A).

189 Thirty five porphyritic spherules with different textures and chemical compositions
 190 were selected for oxygen isotope studies (Fig. 1e,f; Appendix A, B). The presence of zoning
 191 in the relict grains of the spherules indicates that heating has not completely altered their
 192 chemical properties, and that the original oxygen isotopic compositions, may have been
 193 preserved. Oxygen isotope compositions in olivine grains of porphyritic spherules show a
 194 wide spread with $\delta^{18}\text{O}$ from -9 to 40‰ , $\delta^{17}\text{O}$ from -12 to 22‰ , and $\Delta^{17}\text{O}$ lying between -11
 195 to -2‰ (Fig. 2c, Table 1). The distribution of many of the analyses is parallel to, but below,
 196 the TF line.

The typical grain size of olivine in barred olivine spherules is very small, and hence it is difficult to make ion microprobe spot analyses on them. In the absence of wide bars of olivine, bulk oxygen isotope analyses of barred olivine spherules are usually reported using ion microprobe (Engrand et al., 2005; Yada et al., 2005). Here we have identified two barred spherules with large size olivine bars that are uncommon, on which we were able to obtain ion microprobe analyses (Fig. 1g,h). Individual $\delta^{18}\text{O}$ values vary from 21 to 30‰, $\delta^{17}\text{O}$ varies from 6 to 12‰ with $\Delta^{17}\text{O}$ lying between -7 to -3 ‰ (Fig. 2d, Table 1).

5. DISCUSSION

5.1. OLIVINE IN COSMIC SPHERULES AND ITS RELATION TO CHONDRITES

Olivine is a common mineral in both carbonaceous (C) and ordinary (O) chondrites. It has a wide range of compositions in the major chondritic components, chondrules and matrix, that vary widely in their relative proportions among different chondrite groups (Brearley and Jones, 1998). Both O and C chondrites have abundant Type I (MgO-rich) chondrules which are largely dominated by forsteritic olivine. About 10% of chondrules in C chondrites, and about 60% of chondrules in O chondrites, are Type II chondrules in which olivine is more FeO-rich (e.g. Jones, 2012). Since the sizes of the large sized olivine grains in cosmic spherules are similar to those found in chondrules, this could indicate a chondrule contribution. Matrix is much finer grained than that of chondrules, with grain sizes less than a few μm (Weisberg et al., 2006; Palme et al., 2015). These particular properties of chondrites can be used to interpret observations and trends in cosmic spherules.

The major element composition Fe, Si, Mg of olivine within cosmic spherules can be used to understand the relationships to chondrite components. Minor elements, particularly if they are volatile, can get disturbed during atmospheric entry and inferring the minor element

chemistry from such elements is not consistent invariably. Fig. 4 shows plots of FeO/MgO vs SiO₂/MgO for various materials in C chondrites. Chondrules in carbonaceous chondrites of CO, CR and CV groups are dominated by type I, and olivine from these chondrules has a slight spread in oxide FeO/MgO ratios that are close to zero (Fig. 4), while those from type II chondrules has FeO/MgO ratios around one. The bulk compositions of chondrules from CM chondrites (El-Quss Abu Said, CM; Hezel and Palme, 2010) have low oxide FeO/MgO ratios, while there is spread in oxide SiO₂/MgO ratio corresponding to varying olivine / pyroxene abundances. A similar range would be shown for bulk chondrules from all chondrite groups. The bulk matrix compositions for C chondrites has higher FeO/MgO ratios than chondrule olivine (Fig. 4). In particular, the matrix of CM chondrites has high FeO/MgO values when compared with other carbonaceous chondrite groups, as Fe metal has been oxidized. The strong demarcation of the chondrule olivine and matrix silicate data based on SiO₂/MgO and FeO/MgO is diagnostic to estimate the possible contribution of these two major components of chondrites (chondrule and matrix), in cosmic spherules.

Large olivine grains are more likely to be preserved during atmospheric entry compared to smaller grain sizes. The large olivine grains (>20 µm) have a different chemistry compared to the smaller olivine grains (~ few µm) within the same cosmic spherules (Fig. 4). The large olivines from the scoriaceous spherules have very low oxide FeO/MgO values, similar to compositions of type I chondrule olivine in carbonaceous chondrites. On the other hand, the small olivines from the scoriaceous spherules have high oxide FeO/MgO similar to those seen in the matrix of carbonaceous chondrites. In the relict-bearing spherules some large sized olivine grains are slightly more enriched in oxide FeO/MgO compared to scoriaceous (Fig. 4a & b). Compositions of the large relict grains are similar to chondrules from carbonaceous chondrites. In relict-bearing spherules, the small sized olivine grains spread in FeO/MgO from chondrule to CV matrix compositions (Fig. 4b), although the

majority of the smaller grains are similar to chondrules. We suggest that the scoriaceous and relict-bearing spherules, that contribute to nearly ~10–15% of total micrometeorite flux received, most likely represent a combination of chondrule and matrix components from carbonaceous chondrites. For porphyritic spherules (~20% of total flux received) most large and small olivines have FeO/MgO ratios similar to those of chondrules (Fig. 4c). This is the same for the barred spherules (Fig. 4d). The FeO/MgO compositions indicate that compositions of large olivine grains in relict-bearing, porphyritic and barred cosmic spherules are consistent with an origin from different types of carbonaceous chondrite chondrules. However, the unequilibrated ordinary chondrites (UOCs) seems to have a similar range of olivine chondrule compositions, although type II chondrules are less FeO-rich and the range of chondrule olivine compositions is narrower compared to carbonaceous chondrites (Fig. 5). In contrast, the spread in matrix of UOCs is larger than that in carbonaceous chondrites (Fig. 4 and 5). The cosmic spherules have large sized olivine grains with compositions consistent with chondrules from different types of chondrites, their compositional range seems to be better matched by C chondrite chondrules than compared to UOCs. Also, the small size grains do not show the large spread seen in UOC matrix and match better with C chondrite matrix. Further work on oxygen isotope compositions was performed to make strong association with possible parent bodies.

5.2. OXYGEN ISOTOPE COMPOSITIONS OF OLIVINES IN COSMIC SPHERULES

The oxygen isotopic compositional variation in the S-type spherules is a function of the composition of the parent bodies from which they are derived, their evolution in the parent bodies, and any alteration during atmospheric entry due to atmospheric oxygen exchange and ablation. The bulk oxygen isotope compositions of carbonaceous chondrites

272 fall on or close to the CCAM line, while those of ordinary chondrites lie above the TF line
 273 (Clayton et al., 1991; Clayton and Mayeda, 1999). This is also true for the major components
 274 of chondrites: chondrules have $\Delta^{17}\text{O} < 0\text{‰}$ for carbonaceous and $\geq 0\text{‰}$ for ordinary
 275 chondrites (e.g. Clayton et al., 1991; Bridges et al., 1998; Clayton and Mayeda, 1999; Jones
 276 et al., 2004; Kita et al., 2010; Rudraswami et al., 2011b; Ushikubo et al., 2012, 2013; Tenner
 277 et al., 2013, 2015). The oxygen isotope analyses done on micrometeorites/cosmic spherules
 278 by various researchers suggest that they have provenance of carbonaceous chondrites, even
 279 though many show disturbance during atmospheric entry (Engrand et al., 1999, 2005;
 280 Gounelle et al., 2005; Yada et al., 2005; Suavet et al., 2010; Cordier and Folco, 2014;
 281 Rudraswami et al., 2015b). However, the $\delta^{17,18}\text{O}$ values in the individual olivine grains of
 282 small sized (<few hundred μm) micrometeorites/cosmic spherules appear to be principally
 283 dominated by carbonaceous chondrite precursors with only a very small fraction possibly
 284 relating to ordinary chondrites, unlike that as suggested by Suavet et al. (2010). We
 285 measured a few oxygen isotope compositions that lie above the TF line (e.g. Fig. 2b) that
 286 could have be derived from O chondrites. An increase in $\delta^{18}\text{O}$ values due to heating
 287 experienced by the cosmic spherules during atmospheric entry seems highly plausible
 288 (Engrand et al., 2005; Yada et al., 2005; Suavet et al., 2010; Rudraswami et al., 2015b). This
 289 is evident from the difference in $\delta^{18}\text{O}$ in small size grains when compared with those having
 290 large sizes within the same cosmic spherules (Engrand et al., 2005). Given the same chemical
 291 composition and size the grains that are situated close to edge of a spherule are more prone to
 292 exchange of atmospheric oxygen. The upper atmosphere at an altitude of ~ 60 km has $\delta^{18}\text{O} \sim$
 293 23.5‰ (Thiemens et al., 1995). Atmospheric oxygen plays a crucial role in changing the
 294 oxygen isotopic composition of the olivine grains in the cosmic spherules and will have an
 295 impact on interpreting the original isotopic compositions of the spherules. The amount of

change taking place during its short interaction of ~10–15 seconds with the atmosphere is very difficult to estimate (Yu et al., 1995; Yada et al., 2005). However some spherules have olivine grains close to the atmospheric values (Fig. 2). Oxygen diffusion in olivine is very slow, and solid-state oxygen-isotope exchange in olivine is not possible during atmospheric entry. However, if an olivine grain was re-crystallized from melt, then it will record the isotopic composition of the melt that has undergone rapid exchange with the surrounding atmosphere (Fagan et al., 2004; Yada et al., 2005). In addition, many grains have higher $\delta^{18}\text{O}$ values, which extend in the same trend beyond the atmospheric value, can be related to evaporation of mass from the particle (e.g. Fig 2c). Two grains located at the edge of porphyritic spherule AAS62-32-P15 (Fig. 3i), with similar forsterite compositions (~Fo77) and similar sizes, have oxygen isotope compositions of $\delta^{18}\text{O} \sim 23 \text{ ‰}$, similar to those of the upper atmosphere. The oxygen isotope exchange depends on the oxygen density, and requires a prolonged heating event to equilibrate with atmospheric oxygen. The size of the grain and mineralogical composition is vital for modifying the oxygen isotope composition. Larger forsterite grains have less atmospheric oxygen exchange compared to small grains of similar composition as is evident from some of the spherules, e.g. AAS38-204-P62; AAS38-204-P60; AAS62-61-P107; AAS38-167-P79 (Appendix A, B and Fig. 3). The oxygen isotopic composition of the AAS38-204-P62 (Fig. 1c) with a large grain seems to have preserved the original isotopic composition largely, plus smaller grains that shifted to TF line (Fig. 3e). This is true for AAS62-61-P107 (Fig. 3g) where the relict grain is on CCAM line and the other three smaller and similar sized grains are on the TFL near the stratospheric atmospheric value, and a similar trend is seen in AAS38-204-P60 (Fig. 3f). Oxygen isotope analysis of grains with similar fosteritic composition but with different grain size in AAS38-167-P79 (Fig. 3h) shows only a small difference in $\Delta^{17}\text{O}$ values of ~1‰ but a large difference in $\delta^{18}\text{O}$ values.

The fusion crusts of the Murchison (CM) and Allende (CV) chondrites show higher $\delta^{18}\text{O}$ compared to the interior chondrite region which is related to atmospheric oxygen exchange during entry, is also true for ordinary chondrites (Clayton et al., 1986; Hezel et al., 2015). However, oxygen isotope exchange in fusion crusts during atmospheric entry has changed $\delta^{18}\text{O}$ by only a few per mil and $\Delta^{17}\text{O}$ values to $\leq 1\text{‰}$. Furthermore, laboratory heating experiments conducted on Murchison (CM) chondrite up to 1000 °C in a closed system suggest an increase in $\delta^{18}\text{O}$ up to a few per mil, but this has no major bearing on the $\Delta^{17}\text{O}$ values (Clayton et al., 1997). The compiled oxygen isotope data of barred cosmic spherules (Engrand et al., 2005; Yada et al., 2005; Suavet et al., 2010: Fig. 8), that has experienced $\sim 1700^\circ\text{C}$, show a marginal increase in $\Delta^{17}\text{O}$ values along with a large increase in $\delta^{18}\text{O}$ values, suggesting that the atmospheric oxygen exchange in the melted cosmic spherules has very limited influence on the $\Delta^{17}\text{O}$ values. The data of barred spherules can be divided into two groups: a) Group I have $\Delta^{17}\text{O}$ values close to or above the TFL (ellipse and circle in Fig. 6) and b) Group II lie below the TFL (rectangle in Fig. 6). Group II has an increasing trend of $\Delta^{17}\text{O}$ with respect to $\delta^{18}\text{O}$ values. The slope of the line suggests $\sim 1\text{‰}$ change in $\Delta^{17}\text{O}$ for change in $\delta^{18}\text{O}$ of $\sim 10\text{‰}$. The ellipse and circle (group I) marked in Fig. 6 are probably due to the different initial $\delta^{18}\text{O}$ and $\Delta^{17}\text{O}$ of the precursor that has much higher values than those found from the main stream of the particles (rectangle). The large value of $\delta^{18}\text{O}$ in some particles (circle) is probably due to large scale vaporization in addition to atmospheric exchange (Engrand et al., 2005).

In our spherules, mass dependent fractionation in one of the porphyritic spherules, AAS62-32-P18, probably occurred during atmospheric entry. The shift in $\delta^{18}\text{O}$ to $\sim 37\text{--}40\text{‰}$ of olivine grains in this spherule (last two data points on the extreme right hand side of Fig. 7) has resulted in $\Delta^{17}\text{O}$ values slightly above the TF line (Table 1 and Appendix A) from the

initial composition of $\Delta^{17}\text{O}$ values ~ -4 to -2 ‰. Hence, some of the spherules with high $\delta^{18}\text{O}$ values and low $\Delta^{17}\text{O}$ values (as seen on right hand side of Fig. 7) may be attributed to varied precursor materials from carbonaceous chondrites.

5.3. IDENTIFYING PRECURSORS OF THE COSMIC SPHERULES

Most of the olivine analyses from different types of cosmic spherules have $\Delta^{17}\text{O}$ values between -4 to -2 ‰, with $\leq 5\%$ having positive values (Fig. 8), indicating affinity to carbonaceous chondrites for a majority of grains. The distribution in this histogram is consistent with a compilation of literature data shown in Fig. 9 of Rudraswami et al. (2015b). Positive $\Delta^{17}\text{O}$ values in $\sim 30\%$ of the particles measured by Suavet et al. (2010) are suggested to be from ordinary chondritic precursors, which is also consistent with the larger diameters of the spherules measured in that study. However, this does not seem to be the case for spherules that are predominately in the size range of ~ 150 – 250 μm . These sizes mostly show $\Delta^{17}\text{O}$ similar to those found in carbonaceous chondrites (Engrand et al., 1999, 2005; Yada et al., 2005; Rudraswami et al., 2015b). Irrespective of the texture the $\Delta^{17}\text{O}$ values seems to have retained by the cosmic spherules. The change in $\delta^{18}\text{O}$ has not led to modify the $\Delta^{17}\text{O}$ values significantly, indicating that temperature range experienced by different types of cosmic spherule during atmospheric entry do retain the $\Delta^{17}\text{O}$ values in olivine grains that can be used to relate to precursors. The study indicates that in the dominant size range (~ 100 – 250 μm) of the cosmic spherules flux the major contribution of $>90\%$ comes from carbonaceous chondrites. As the size increase, the contribution of the ordinary chondrites towards the flux increases as seen in Suavet et al. (2010). The scoriaceous and relict bearing spherules that have experienced partial melting have oxygen isotopic values consistent with that seen in

carbonaceous chondrites, except a few that seemed to have undergone large atmospheric exchange (Figs. 3, 7). The porphyritic that have experienced more heating than scoriaceous and relict bearing spherules have large spread in $\delta^{18}\text{O}$ values, but $\Delta^{17}\text{O} < 0$ and within the range as observed in carbonaceous chondrites, so is also true for barred spherules (Figs. 7, 8). One of the spherules, AAS38-169-P59, has a large olivine relict grain that has a $\Delta^{17}\text{O}$ value of 5.7‰ with relatively low $\delta^{17}\text{O}$ (7.6‰) and $\delta^{18}\text{O}$ (3.5‰) values (Figs. 3a). This grain may have originated from a different type of chondrite that contains ^{16}O -poor material. The grain seems to be a part of a porphyritic olivine chondrule. A very high $\Delta^{17}\text{O}$ (~13‰) value observed by Yada et al. (2005) in cryptocrystalline spherule M03KS063 ($\delta^{18}\text{O} = 51.8\text{‰}$, $\delta^{17}\text{O} = 40\text{‰}$) was interpreted to be derived from a ^{16}O -poor body. The possibility of R-chondrite material being the precursor for the olivine grain in AAS38-169-P59 is ruled out as R chondrites have $\Delta^{17}\text{O}$ values only as high as ~3‰ (Kallemeyn et al., 1996; Fig. 7). Our interpretation is that the high $\Delta^{17}\text{O}$ observed in the spherule AAS38-169-P59 is the result of ^{16}O -poor and high $\Delta^{17}\text{O}$ precursor properties. The possibility of oxygen isotope exchange for spherule AAS38-169-P59 during atmospheric entry that has pushed $\Delta^{17}\text{O}$ values to such a high value is unlikely as oxygen is a minor constituent at high altitude (Thiemens et al., 1995; Yada et al., 2005). If the above is true then the oxygen isotopic composition in the solar nebula may be considerably more heterogeneous than is currently assumed, based on meteorite studies alone.

The bulk oxygen isotope ratios of cosmic spherules that contain olivine grains of different sizes with different forsterite contents, along with other minerals, can lead to changes in $\Delta^{17}\text{O}$ values during atmospheric entry. The majority of the data have $\Delta^{17}\text{O}$ below the TF line, with a few exceptions that can be attributed to alteration during entry or possibly derivation from ordinary chondrites (Fig. 7). There are some spherules (e.g. AAS38-188-P72,

AAS38-204-P68, AAS62-32-P18, and AAS38-204-P16) that have $\Delta^{17}\text{O}$ lying between 0 to 2 ‰ similar to those seen in ordinary chondrites. Even the large value of $\delta^{18}\text{O}$ has not been able to alter the $\Delta^{17}\text{O}$ values significantly above the TF line (Fig. 7). In addition, the FeO/MgO versus SiO₂/MgO of large olivine grains in cosmic spherules with different textures are similar to chondrules (Fig. 4). Matrix in CI and CM chondrites has $\Delta^{17}\text{O}$ values close to TFL (Rowe et al., 1994) suggesting some spherules may possibly have CI and CM chondritic precursors. The scoriaceous spherules can be associated with matrix type material predominantly found in CI or CM chondrites. However, relict grain bearing spherules can be partially associated with CI/CM and with other carbonaceous chondrites which have higher abundances of chondrules such as CO, CV, CK, CR (Fig. 4). The chondrule dominance is also visible in porphyritic spherules and barred spherules. Since chondrules are a major component in carbonaceous chondrites (except CI and CM), with $\Delta^{17}\text{O}$ values similar to those seen in cosmic spherules, we suggest that carbonaceous chondrites chondrules could be a major component of the micrometeorite flux. The high porosity of the carbonaceous chondrites (~40–60%) compared to ordinary chondrites (~20–30%) has the advantage of liberating a large amount of dust in a smaller size range during catastrophic collisions (Britt et al., 2002; Consolmagno et al., 2008), which would be consistent with the micrometeorite flux being dominated by carbonaceous chondrite material. In contrast, collision involving ordinary chondrites may release relatively larger sized particles, and the oxygen isotope composition of large cosmic spherules analyzed seem consistent with them (Suavet et al., 2010).

6. CONCLUSIONS

Understanding the chemical and isotopic composition of extraterrestrial particles is central for understanding Solar System evolution. However, for cosmic spherules there are limitations on our understanding as cosmic spherules change their original compositions as they enter the Earth's atmosphere. In our study, oxygen isotope compositions in a majority of olivine grains from different textural types of cosmic spherules range from -4 to -2% in $\Delta^{17}\text{O}$ values. The oxygen isotopic composition of olivines in cosmic spherules indicates that chondrules and isolated grains from carbonaceous chondrites have largely contributed to the flux of the micrometeorites. AAS38-169-P59 has a $\Delta^{17}\text{O} \sim 5.7\%$, suggesting it to originate from some unidentified source. In addition, a small fraction of cosmic spherules display oxygen isotope evidence that can be possibly related to ordinary chondrites.

FIGURE CAPTIONS

Figure 1.

Representative backscattered electron (BSE) images of different types of cosmic spherules: a and b): scoriaceous; c and d): relict grain bearing; e and f): porphyritic; g and h): barred. The circles indicate the regions of ion microprobe analyses and the numbers are the $\Delta^{17}\text{O}$ values for that particular analysis. The chemical compositions and oxygen isotope data of the region of analyses are provided in Appendix B and Table 1, respectively.

Figure 2.

Oxygen isotope compositions of different types of cosmic spherules: a) scoriaceous, b) relict grain bearing, c) porphyritic and d) barred, measured using ion microprobe. The star symbol is for stratospheric oxygen isotope composition. BSE images of the cosmic spherules and the regions of analyses are shown in Appendix A. The solid lines labelled are the terrestrial fractionation (TF) line, having slope of ~ 0.52 , and the carbonaceous chondrite anhydrous mineral (CCAM) line, with a slope of ~ 0.94 (Clayton et al., 1993). All error bars are 2σ .

Figure 3.

Oxygen isotope compositions of relict-bearing and porphyritic cosmic spherules whose BSE images are shown in Appendix A. The solid lines are terrestrial fractionation (TF) and chondrite anhydrous mineral (CCAM) lines, having slope of ~ 0.52 and ~ 0.94 , respectively

(Clayton et al., 1993). All error bars are 2σ . Appendix B and Tables 1 provide the chemical composition and oxygen isotopic data of spherules.

Figure 4.

Oxide FeO/MgO vs. SiO₂/MgO of large ($\geq 20\ \mu\text{m}$) and smaller sized ($\sim\text{few}\ \mu\text{m}$) olivines for different types of cosmic spherules, compared with olivine compositions of chondrules, except for CM chondrules (bulks), and bulk matrix compositions from several carbonaceous chondrites. The data of chondrules (Allende CV: Rudraswami et al., (2011b); MET 00426 (CR) and QUE99177 (CR): Tenner et al. (2015); Y-81020 (CO): Tenner et al. (2013); El Quess Abu Said (CM): Palme et al. (2015)) and matrix (Mokoia (CV), Efremovka (CV), Renazzo (CR), Kainsaz (CO), El-Quss Abu Said (CM): Palme et al. (2015)) of different carbonaceous chondrites are included for comparison. The regions defined by chondrules and matrix are identified in Fig.4a.

Figure 5.

Oxide FeO/MgO vs. SiO₂/MgO of large ($\geq 20\ \mu\text{m}$) and smaller sized ($\sim\text{few}\ \mu\text{m}$) olivines for different types of cosmic spherules, compared with olivine compositions of chondrules and bulk matrix compositions from several unequilibrated ordinary chondrites (UOCs, Rudraswami, 2009). The data for matrix are taken from Matsunami et al. (1990), Hutchison et al. (1987) and Weisberg et al. (1997).

Figure 6.

Plot of $\Delta^{17}\text{O}$ vs. $\delta^{18}\text{O}$ of different types of spherules analysed in this study. Most of the data lie below the TF line which indicates that the micrometeorite flux is dominated by carbonaceous chondrites. The ellipse and rectangle areas are for the ordinary and R chondrites, respectively (Clayton et al., 1991; Clayton and Mayeda, 1999). The atmospheric data is shown by asterisk (Thiemens et al., 1995). Some of the data lying above the TF line may be derived from ordinary chondrites, however, AAS38-169-P59 has $\Delta^{17}\text{O} \sim 5.7\text{‰}$ that may be from a previously un-sampled isotopic reservoir. All error bars are 2σ .

Figure 7.

Plot of $\Delta^{17}\text{O}$ vs. $\delta^{18}\text{O}$ of barred spherules measured using IR-laser fluorination coupled with mass spectrometry (Suavet et al., 2010) and ion microprobe (Engrand et al., 2005; Yada et al., 2005; this work). Ion microprobe data from previous studies were measured using a defocused primary beam, providing data similar to those of bulk chemical composition. The barred spherule data can be divided into two groups: one with $\Delta^{17}\text{O} \geq 0$ (marked ellipse and circle) and the other with < 0 (marked square). The data with $\Delta^{17}\text{O} < 0$ shows an increase in $\Delta^{17}\text{O}$ as $\delta^{18}\text{O}$ values goes up.

Figure 8.

Histogram of $\Delta^{17}\text{O}$ of olivine grains in different types of cosmic spherules analysed in this study.
