Support for Relatives Bereaved by Psychiatric Patient Suicide: National Confidential Inquiry Into Suicide and Homicide Findings

Objectives: International suicide prevention strategies recommend providing support to families bereaved by suicide. The study objectives were to measure the proportion of cases in which psychiatric professionals contact next of kin after a patient’s suicide and to investigate whether specific, potentially stigmatizing patient characteristics influence whether the family is contacted.

Methods: Annual survey data from England and Wales (2003–2012) were used to identify 11,572 suicide cases among psychiatric patients. Multivariate regression analysis was used to describe the association between specific covariates (chosen on the basis of clinical judgment and the published literature) and the probability that psychiatric staff would contact bereaved relatives of the deceased.

Results: Relatives were not contacted after the death in 33% of cases. Contrary to the hypothesis, a violent method of suicide was independently associated with greater likelihood of contact with relatives (adjusted odds ratio=1.67). Four patient factors (forensic history, unemployment, and primary diagnosis of alcohol or drug dependence or misuse) were independently associated with less likelihood of contact with relatives. Patients’ race-ethnicity and recent alcohol or drug misuse were not associated with contact with relatives.

Conclusions: Four stigmatizing patient-related factors reduced the likelihood of contacting next of kin after patient suicide, suggesting inequitable access to support after a potentially traumatic bereavement. Given the association of suicide bereavement with suicide attempt, and the possibility of relatives’ shared risk factors for suicide, British psychiatric services should provide more support to relatives after patient suicide.

Psychiatric Services in Advance (doi: 10.1176/appi.ps.201600004)

Approximately 6,000 people die by suicide in the United Kingdom annually (1), with each suicide estimated to affect six (2) to 60 (3) friends and relatives. These reports suggest that the annual incidence of persons who are bereaved by suicide in the United Kingdom is between 36,000 and 360,000. International studies comparing health outcomes after various types of bereavement show that people bereaved by suicide have an increased risk of suicide and psychiatric admission (4). In Britain, people bereaved by suicide, regardless of whether they are related to the deceased by blood, have an increased risk of suicide attempt and poor occupational functioning (5) and significantly higher stigma, shame, responsibility, and guilt scores (6) compared with people bereaved by other causes of sudden death. Such stigma is thought to limit help-seeking behavior and offers of support (7–10).

The suicide prevention strategies for England (11), the United States (12), and other high-income countries recommend providing support for people bereaved by suicide. The evidence base for this recommendation is limited (13), but a number of initiatives to support persons bereaved by suicide are in development in the United Kingdom (14), and they will require evaluation. To ensure equitable access to such services, particularly among the most marginalized groups, it is important to understand and address stigmatizing or avoidant attitudes toward people bereaved by suicide.

In Britain, there is no clear framework for providing National Health Service (NHS) or social services support to people bereaved by suicide, and the voluntary sector provides the majority of support (15). An exception is made for suicides of patients recently under the care of psychiatric services, constituting approximately 30% of general population suicides (1). In the case of these patients, NHS guidelines recommend that clinical teams offer families and carers “prompt and open information” and “appropriate and effective support” and involve them in a routine postsuicide review (16). No previous studies have explored the extent to which relatives are offered such support, despite growing evidence describing the vulnerabilities of persons bereaved by suicide (4,5). Psychiatric services that involve family members in
postsuicide multidisciplinary reviews have shown local reductions in suicide rates, suggesting systemic benefits (17). Failure to offer support after a patient’s suicide represents a missed opportunity to modify adverse mental health outcomes.

Our objective was to use data from the National Confidential Inquiry Into Suicide and Homicide (NCISH) to describe the proportion of relatives contacted after a psychiatric patient’s suicide in England and Wales. We hypothesized that psychiatric teams would not make contact with families and carers after every suicide, even if patients were documented as living with family or friends, and that specific, potentially stigmatizing characteristics of the patients would influence the likelihood of contacting relatives. Such characteristics were selected on the basis of research identifying characteristics implicated in inequitable provision of any health services. We also judged that use of a violent suicide method might dissuade staff from contacting relatives because of social distaste or embarrassment, components of the stigma associated with suicide bereavement (7–9).

METHODS

Case Ascertainment

Annual NCISH survey data were used to identify individuals who had died by suicide between January 1, 2003, and December 31, 2012, in England and Wales. The NCISH methods have been described in detail elsewhere (18,19). First, information on all deaths in England and Wales that received a coroner’s verdict of suicide or an open verdict (because doubt remained over cause) was obtained from the Office for National Statistics (ONS). Open verdicts were included, by United Kingdom convention, because the majority are understood to be suicide cases (20). Second, information on whether the deceased had been in contact with psychiatric services in the 12 months before death was obtained from the NHS trusts in the deceased’s district of residence. Third, demographic and clinical data about the patients who had been in contact with services before their death were obtained by sending a questionnaire to the responsible consultant psychiatrist.

NCISH has research ethics approval from the North West Research Ethical Committee and approval under Section 60 of the Mental Health and Social Care Act.

Key Covariates

Our primary outcome was whether the relatives of patients who died by suicide had been contacted by the psychiatric team after the patient’s death. This was measured by fixed-choice responses to the question “Have you (or any other member of your mental health team) had contact with relatives of the patient following his/her death?” Responses that endorsed “none” were coded as negative, and those that endorsed “letter,” “face-to-face discussion,” and “telephone discussion” were coded as positive. There was also a choice for “other,” which permitted free-text responses. These remarks were coded subjectively by the first and second authors. Contacts made at an inquest or funeral were coded as negative because they were felt to constitute excessive delay and an inappropriate context (21) and to lack the proactivity of a direct contact. The data set contained no variable recording presence or absence of next-of-kin details, apart from any comments entered in the “other” category. Our secondary outcome was a dichotomous measure of whether a contact was made face-to-face or by letter or telephone call.

We used clinical judgment and the stigma literature to identify potentially stigmatizing sociodemographic and clinical characteristics of psychiatric patients that we predicted would dissuade psychiatric teams from contacting relatives after a suicide. These characteristics included use of a violent suicide method (6), living with a partner or a dependent who was also a psychiatric patient (22), unemployment (23), minority racial or ethnic group (24), residence in the United Kingdom for less than five years (25), forensic history (26), childhood abuse history (27), recent alcohol misuse (28), recent drug misuse (28), primary diagnosis of alcohol dependence or misuse (29), and primary diagnosis of drug dependence or misuse (28). We used the ONS suicide classification to define dying by violent means: hanging/strangulation, jumping (from a height/in front of a moving vehicle), firearms, cutting/stabbing, burning, drowning, electrocution, and asphyxiation/suffocation. Non-violent deaths were classified as deaths by self-poisoning and by carbon monoxide poisoning (30).

Five potential confounders were selected a priori on the basis of clinical judgment: age, sex, socioeconomic status (using employment as a proxy measure), severe mental illness (schizophrenia or bipolar disorder), and personality disorder. These diagnoses were used to capture the stigma of impaired functioning—as distinct from the stigma of accessing mental health services, however briefly—and to capture negative attitudes among psychiatric professionals toward this patient group (31,32).

Statistical Analysis

Descriptive statistics are presented as absolute numbers and proportions, and chi-square tests (with a two-sided p value threshold of <.05) were used to compare outcomes by patient characteristic. We used logistic regression to estimate the strength of the univariate association between each characteristic and outcomes. Models were adjusted for the five confounders identified above, presenting odds ratios (ORs) and their 95% confidence intervals (CIs). Next, we used multivariate logistic regression of all significant stigmatizing characteristics in the univariate analysis to identify statistically significant independent variables. Collinearity of substance misuse variables was insufficiently high to warrant dropping them from the model. Variables for which data were available only for 2011–2012 (living with a partner/dependent who was also a psychiatric patient, recent United Kingdom residency, and childhood abuse history) were not entered into this stage of the analysis for reasons of power. Therefore, the final multivariate logistic regression analysis investigated associations with eight potentially stigmatizing variables.
We used complete-case analysis in relation to missing data, such that if an item of information was not known, the case was removed from the analysis of that item. The denominator in all estimates is therefore the number of valid cases for each item.

All analyses were conducted by using Stata 13.0 software (33).

Sensitivity Analyses
We conducted four sensitivity analyses to assess robustness of findings. Given the possibility that some patients lacked next-of-kin details, we simulated exclusion of those with a higher likelihood of having no next of kin listed: those who were widowed, separated, or divorced or who were not living with family members (N=2,881). We excluded patients with an open verdict. We assessed the effect of missing data for whether contact was made with relatives by including cases previously excluded on that basis, recoding the missing values as no contact. Finally, we assessed whether likelihood of making contact with relatives was influenced by recent patient contact by repeating our main analysis but additionally adjusting for a binary variable describing contact within three months of suicide.

RESULTS
Over the study period (January 1, 2003, to December 31, 2012), NCISH received notifications of 47,824 suicides in England and Wales, including 35,091 cases in which the coroner’s verdict was suicide and 12,733 open verdicts or deaths from undetermined cause. Of these, 13,243 (28%) cases were confirmed to be patients who had been in contact with NHS psychiatric services in the year prior to death. Completed questionnaires were received for 13,033 cases, a response rate of 98% (Figure 1). Details of whether postsuicide contact had been made with relatives were lacking for 1,461 (11%) cases, which were excluded from this analysis. We included the remaining 11,572 suicide cases in the analyses. Levels of missing data were minimal, ranging from 0% to 9%.

The sample was primarily male (66%) and white (92%), and most patients had used a violent suicide method (72%) (Table 1). Approximately half the sample had lived alone (46%), whereas 52% had cohabited with family (spouse or partner, parents, or children) or friends.

No contact had been made with relatives after 3,790 suicides (33%). Of the 7,782 suicides (67%) following which relatives were contacted, 61% (N=4,755) of contacts were made face-to-face, 28% (N=2,177) by telephone call, and 11% (N=843) by letter. During 2003–2012, the annual proportion of suicide cases for which relatives were contacted ranged from 63% to 70%, and there were no significant temporal changes over time (likelihood-ratio \( \chi^2 \) test for linear trend) (Figure 2).

The results of our univariate logistic regression analyses showed that several potentially stigmatizing patient characteristics (forensic history, unemployment, recent alcohol misuse, recent drug misuse, primary diagnosis of alcohol dependence or misuse, and primary diagnosis of drug dependence or misuse) were associated with a lesser likelihood that psychiatric staff contacted relatives of a patient after the patient’s suicide (Table 2). Violent method of suicide was associated with a significantly greater probability that staff contacted relatives, as was living with a partner or dependent who also was a psychiatric patient.

Results from our multivariate logistic regression analyses showed that, contrary to our hypothesis, a violent method of suicide was independently associated with a greater likelihood of contacting relatives (adjusted OR [AOR]=1.67) (Table 3). Patient characteristics independently associated with not contacting relatives were unemployment (AOR=.80), forensic history (AOR=.69), primary diagnosis of alcohol dependence or misuse (AOR=.46), and primary diagnosis of drug dependence or misuse (AOR=.48). No other potentially stigmatizing patient characteristics were significantly associated with probability of staff’s making contact with relatives.

Multivariate analysis for our secondary outcome showed that only primary diagnosis of alcohol dependence or misuse was associated with lower odds of being contacted face-to-face versus by letter or telephone (AOR=.62) (Table 3). Again, contrary to our hypothesis, use of a violent method was associated with an increased likelihood of face-to-face contact (AOR=1.28).

In an analysis excluding patients who were not as likely to have listed next of kin, the magnitude of the ORs for our outcomes were only marginally changed. In analyses that excluded patients with an open verdict and included patients with missing values for contact (recoded as no contact), our findings were unchanged.

In an analysis adjusted for recent patient contact, recent alcohol misuse was significantly associated with lower odds of contacting relatives (AOR=.85, CI=.75–.96), unlike the findings of our main analysis. [Tables presenting the results of the sensitivity analyses are available as an online supplement to this article.]

DISCUSSION
For a third of cases in our national sample, relatives bereaved by patient suicide had not been contacted by the psychiatric team.
involved, even for the third of those patients who were living with a partner, family, or friends. This pattern occurred despite clear NHS recommendations that providers of psychiatric services should contact relatives after all cases of patient suicide (16). Whereas some of those patients may have chosen not to provide next-of-kin details, this figure raises concerns about inequalities in the support offered to psychiatric patients’ relatives after a potentially traumatic bereavement. Unless there

SUPPORT FOR RELATIVES BEREAVED BY PSYCHIATRIC PATIENT SUICIDE
were clear circumstances in which contacting household members was inadvisable, such as breaching confidentiality, our findings suggest a need for more proactive outreach after patient suicide. Furthermore, our hypothesis-based analysis demonstrated that these inequalities constituted inequities, given that potentially stigmatizing characteristics of the deceased were associated with a reduced likelihood of contacting relatives, including a forensic history, unemployment, and a primary diagnosis of alcohol dependence or misuse or drug dependence or misuse. These results suggest that such patients’ families are being avoided because of generalized stigma, resulting in the neglect of their needs and raising concerns about the likelihood of neglecting patients’ needs (34).

Above and beyond these clinical governance issues, our findings are concerning because such characteristics are likely to be shared with bereaved relatives, and many of these characteristics are regarded themselves as risk factors for suicide (11). These and other shared familial and environmental risk factors for mental illness and suicidal behavior (35,36), together with the additional risk conferred by suicide bereavement (4,5), identifies this group of relatives as being at higher risk of suicidal behavior. Their help-seeking behavior is likely to have been conditioned by the stigma associated with their relative’s mental illness (37) and further influenced by the stigma of suicide (6–9). Consequently, such patient characteristics should alert staff to a greater need to support such relatives after suicide rather than as reasons to marginalize them in this way.

Contrary to our prediction that a violent method of suicide would dissuade staff from contacting relatives, a violent mode of suicide increased the probability of contact, primarily in person. This finding suggests that staff responded appropriately to the anticipated distress of a violent suicide, in contrast to the lay public, who tend to withdraw through social distaste or embarrassment (7–10). Because violent suicide is associated with more severe and comorbid mental illness (38), this finding may also reflect a tendency by staff to contact relatives who were well known to the service.

The strengths of this study were that it used a national, comprehensive sample of all suicides among patients with recent contact with psychiatric services, benchmarking expected standards of post-suicide support against national guidelines (16). Only one other published study in the United Kingdom has described support offered to those bereaved by suicide, recruiting a sample of 85 friends and relatives of older adults (39). Our use of routine data reduced the risk that bias might explain the findings, which were robust to sensitivity analyses. We prespecified predictor variables, reducing the likelihood that chance might account for associations identified. Alternative explanations for the negative associations between patient characteristics and contact with relatives are that these factors might themselves reduce the likelihood of a patient’s providing details of next of kin. In some cases they could be markers of disrupted family and social networks, influencing professionals’ relationships with relatives before the suicide and their anticipation of the families’ reaction if contacted.

The study’s main limitation lay in using routine data. The data set lacked a variable describing presence or absence of next-of-kin details, beyond the six cases in which the availability of next-of-kin data was specifically documented. However, our main findings were robust to a sensitivity analysis that excluded cases with a higher likelihood of not having next-of-kin data. We excluded cases (11%) in which it was unknown whether contact with relatives had taken place. In some cases in which completing psychiatrists endorsed none, they may have omitted mentioning that there were no next-of-kin details or may have been unaware of colleagues’ communications. Our analysis used employment status as a proxy for deprivation but did not capture area-level deprivation or describe geographic variation in outcomes. Understanding the influence of these variables would assist service improvements.

Our secondary outcome captured the mode of contact after patient suicide but not its therapeutic quality. In some cases, contact may have been made to notify relatives of the death rather than to offer condolences or sources of support. The routine data set lacked a variable describing whether staff had met relatives before the death, which might influence postsuicide contact, as well as any sociodemographic characteristics of the next of kin. It also lacked information on which individuals in the sample had been formally discharged from psychiatric care within 12 months of their deaths and how soon after the discharge the suicide occurred. In some cases, teams may have been unaware of the patient’s death. However, our findings were robust to adjustment for recent contact with the patient, suggesting that the timing of the most recent contact did not strongly influence postsuicide support. Moreover, all such cases require postsuicide review involving relatives, even if discharge had been a year.
before death, and therefore represent missed opportunities to learn lessons, particularly for patients affected by unemployment, criminality, and substance misuse. Improving recording of next-of-kin details and involving families in case review should open up communication channels, providing a natural context in which to offer information and support.

Educating psychiatric professionals about the vulnerabilities of people bereaved by suicide is important (40) and has the potential to address the inequities uncovered in this study. Directing relatives of patients who die by suicide to support services (15) is recommended (40), but no United Kingdom studies have described the use of NHS and voluntary-sector services for this purpose. Qualitative interviews with British general practitioners indicate that although the majority feel a responsibility to contact bereaved patients, particularly after traumatic bereavement (41), many feel unprepared to deal with the specific effects of suicide, welcoming guidance on what approach to take (42). Their uncertainty is compounded by a lack of evidence for effective interventions to reduce the risk of suicide and psychopathology (13). Each suicide affects a network of relatives, former partners, and friends (3) that extends well beyond the majority feel a responsibility to contact bereaved next of kin. Even if immediate family are offered professional support, other members of the patient’s network may be overlooked. National marketing of bereavement support available by self-referral would help address the needs of the “hidden” bereaved and reduce the barriers to help seeking created by the stigma of suicide bereavement (7–9).

a Adjusted odds ratios (AORs) were adjusted for age, sex, unemployment, severe mental illness (schizophrenia or bipolar disorder), and personality disorder.

b The analysis was a multivariate logistic regression of all potentially stigmatizing characteristics for which there were data for each of the years from 2003 to 2012.

The article also provides univariate analysis of associations between characteristics of patients who died by suicide and whether psychiatric staff made contact with their relatives after the death. The table includes data on various factors such as violent method of suicide, employment status, forensic history, and drug misuse. Adjusted odds ratios (AORs) are calculated for each characteristic, adjusted for age, sex, unemployment, severe mental illness (schizophrenia or bipolar disorder), and personality disorder.
by suicide (13), particularly proactive outreach, for which there is an expressed need (44). Primary care and psychiatric professionals are in unique positions to offer such outreach and to counter reluctance to seek help. Health services and academic partners must evaluate such work as part of local and national initiatives to prevent suicide.

CONCLUSIONS

Our study showed that the relatives of over 30% of psychiatric patients who died by suicide in the United Kingdom did not receive postsuicide support from the patients’ psychiatric teams, even if the presence of next of kin could be inferred from living situation. We demonstrated clear inequities in the provision of support for families of unemployed patients, those with a forensic history, and those with a primary diagnosis of alcohol or drug dependence or misuse. Such characteristics, themselves risk factors for suicidal behavior, are often shared with bereaved relatives, for whom suicide bereavement additionally confers an increased risk of suicidality. Improved outreach to relatives after a patient’s suicide has the potential to improve outcomes in a group regarded as having a high risk of suicide, although this possibility requires careful evaluation.
