INTRODUCTION

Major depression has a great burden both in terms of suffering and costs for the society.\(^1\)\(^-\)\(^3\) However, its pathology is still unclear. There is a strong genetic background with risk of first-degree relatives showing a 2.8-fold increase\(^6\)\(^-\)\(^8\) and twin studies suggesting a 37–43% heritability.\(^9\)

Due to its exceptionally large clinical heterogeneity, depression is difficult to study from a genetic point of view.\(^6\) Candidate gene studies select polymorphisms based on linkage studies or hypothetical choices concerning already known etiological mechanisms in the neurobiology of depression. Therefore the scope of investigated polymorphisms is rather narrow in terms of the systems in question.\(^9\) Consistently replicated findings from these studies are few and the identified polymorphisms confer a small amount of risk. In contrast to association studies limited to previous knowledge and researcher preferences, GWAS-s (genome-wide association studies) are more comprehensive and less biased. However, as a major drawback genome-wide significance needs to be set to very low due to the large amount of hypothesis testing. Furthermore, polymorphisms implicated in GWAS studies with at least a suggestive significance often show no connection to mechanisms already implicated in the background of depression.\(^6\)

Although one novel study using a very large cohort but less intensive phenotyping based on self-reported depression identified 15 genetic loci,\(^10\) generally no associations with a genome-wide significance are identified in individual studies in psychiatric patients. A recent meta-analysis of three GWAS-s in major depressive disorder observed the strongest associations for three intronic single-nucleotide polymorphisms (SNPs), including one (rs1106634) in the ATP6V1B2 gene encoding the vacuolar H\(^+\)-ATPase on lifetime and current depression and the possible mediating role of neuroticism by logistic and linear regression in a white European general sample of 2226 subjects. Association of rs1106634 with performance on frontal (Stockings of Cambridge (SOC)) and hippocampal-dependent (paired associates learning (PAL)) cognitive tasks was investigated in multivariate general linear models in a smaller subsample. The ATP6V1B2 rs1106634 A allele had a significant effect on lifetime but not on current depression. The effect of the A allele on lifetime depression was not mediated by neuroticism. The A allele influenced performance on the PAL but not on the SOC test. We conclude that the effects of variation in the vacuolar ATPase may point to a new molecular mechanism that influences the long-term development of depression. This mechanism may involve dysfunction specifically in hippocampal circuitry and cognitive impairment that characterizes recurrent and chronic depression.

Association of ATP6V1B2 rs1106634 with lifetime risk of depression and hippocampal neurocognitive deficits: possible novel mechanisms in the etiopathology of depression

X Gonda\(^1\)\(^-\)\(^2\)\(^-\)\(^3\), N Eszlari\(^2\)\(^-\)\(^3\), IM Anderson\(^4\)\(^-\)\(^5\), JFW Deakin\(^4\)\(^-\)\(^5\)\(^-\)\(^6\), G Bagdy\(^2\)\(^-\)\(^3\) and G Juhasz\(^2\)\(^-\)\(^3\)\(^-\)\(^4\)\(^-\)\(^5\)\(^-\)\(^7\)

Current understanding and treatment of depression is limited to the monoaminergic theory with little knowledge of the involvement of other cellular processes. Genome-wide association studies, however, implicate several novel single-nucleotide polymorphisms with weak but replicable effects and unclarified mechanisms. We investigated the effect of rs1106634 of the ATP6V1B2 gene encoding the vacuolar H\(^+\)-ATPase on lifetime and current depression and the possible mediating role of neuroticism by logistic and linear regression in a white European general sample of 2226 subjects. Association of rs1106634 with performance on frontal (Stockings of Cambridge (SOC)) and hippocampal-dependent (paired associates learning (PAL)) cognitive tasks was investigated in multivariate general linear models in a smaller subsample. The ATP6V1B2 rs1106634 A allele had a significant effect on lifetime but not on current depression. The effect of the A allele on lifetime depression was not mediated by neuroticism. The A allele influenced performance on the PAL but not on the SOC test. We conclude that the effects of variation in the vacuolar ATPase may point to a new molecular mechanism that influences the long-term development of depression. This mechanism may involve dysfunction specifically in hippocampal circuitry and cognitive impairment that characterizes recurrent and chronic depression.

Translational Psychiatry (2016) 6, e945; doi:10.1038/tp.2016.221; published online 8 November 2016
MATERIALS AND METHODS
This present research is part of the NewMood study, funded by the European Union (New Molecules in Mood Disorders, Sixth Framework Program of the EU, LSHM-CT-2004-503474), carried out in accordance with the Declaration of Helsinki, and approved by the local Ethics Committees (Scientific and Research Ethics Committee of the Medical Research Council, Budapest, Hungary; and North Manchester Local Research Ethics Committee, Manchester, UK).

Participants
All participants provided written informed consent. Our study involved two levels, 1 and 2. Level 1 sample was recruited through advertisements and general practices in Budapest, and through advertisements, general practices and a website in Greater Manchester. N = 2226 subjects (n = 904 in Budapest and n = 1322 in Manchester) were successfully genotyped for \textit{ATP6V1B2} rs1106634, and provided information about gender, age, lifetime and current depression by filling out the NewMood questionnaire pack.\textsuperscript{13} All Level 1 subjects were of white European ethnic origin, and had no relatives participating.

Level 2 sample was collected in Manchester. N = 206 subjects (n = 114 having participated in Level 1; and n = 92 new subjects recruited through advertisements) were successfully genotyped for \textit{ATP6V1B2} rs1106634 and interviewed for Montgomery-Åsberg Depression Rating Scale and lifetime depression, provided information about gender, age and neuroticism, and carried out both cognitive tasks.

Phenotypic assessment
Level 1 questionnaire pack included the Brief Symptom Inventory (BSI),\textsuperscript{14} the Big Five Inventory (BFI-44)\textsuperscript{15} and a background questionnaire containing a question about lifetime depression, validated with face-to-face diagnostic interviews in a subsample.\textsuperscript{13} We calculated a continuous weighted score (sum of item scores divided by the number of items completed) for the BSI depression subscale (depression items plus additional items) (BSI-Dep), and for the BFI-44 neuroticism scale and used these variables for the analyses.

In Level 2, we measured lifetime depression with a clinical diagnosis of major depressive disorder: trained researchers administered the Structured Clinical Interview for DSM-IV (SCID-I/NP).\textsuperscript{16} Those with bipolar disorder or any other psychiatric condition except for major depression were excluded from the analyses. Montgomery-Åsberg Depression Rating Scale (MADRS) was used to measure depressive symptoms.\textsuperscript{17} Neuroticism was measured with the neuroticism subscale of the NEO-PI-R.\textsuperscript{18}

In Level 2, to assess neurocognitive endophenotypes of depression, we chose two computerized tasks from the Cambridge Neuropsychological Test Automated Battery software (CANTAB; http://www.cambridgecognition.com/). Paired associates learning (PAL) task assesses episodic memory,
R1106634 A is the minor allele in our sample. Our sample was in Hardy-Weinberg equilibrium (P > 0.05). Description of the Level 1 and 2 samples is shown in Table 1. The Level 1 Budapest and Manchester subsamples differ significantly in all variables except for gender, so including population as a predictor in the regression equations is required. Effect of the A allele on lifetime and current depression

In the combined Level 1 sample, ATP6V1B2 rs1106634 A allele exerts a Bonferroni-corrected significant effect as a risk for lifetime depression in additive and dominant, but not in recessive models (Table 2). Nevertheless, its effect is not significant on BSI depression score in any of the models (Table 2). Post hoc analyses indicated that the risk of the A allele on lifetime depression is replicable in the two subsamples (Table 3).

The mediating role of neuroticism

We investigated whether the effect of ATP6V1B2 rs1106634 A allele on lifetime depression is due to the association of the A allele with higher neuroticism scores. In the combined Level 1 sample, with population, gender and age as covariates, A allele is in a significant positive association with neuroticism score (its $\beta = 0.102; t = 2.722; P = 0.006$ in an additive, and $\beta = 0.114; t = 2.721; P = 0.007$ in a dominant model). Lifetime depression also associates positively to neuroticism ($t = -27.996; P < 0.001$): mean neuroticism score is $3.70 \pm 0.026$ in those who did, and $2.75 \pm 0.022$ in those who did not report lifetime depression. So, we could test the possible mediating role of neuroticism in the effect of the A allele on lifetime depression risk. As post hoc tests with a nominal $P < 0.05$ significance threshold, including neuroticism as an additional covariate in the regression equations, besides population, gender and age, the significant positive effect of A allele on lifetime depression risk decreased but did not disappear: OR = 1.317; $t = 2.566; P = 0.010$ in the additive, and OR = 1.367; $t = 2.622; P = 0.009$ in the dominant model (for comparisons, see Table 2), indicating that the effect of the A allele on depression is not mediated solely by the association of this allele with neuroticism.

Association of the A allele with brain region-specific cognitive performance

Next, we tested post hoc, in Level 2, if ATP6V1B2 rs1106634 A allele explains the variance of performance on the two neurocognitive tasks independently of the variance explained by lifetime depression, current depression and neuroticism. A multivariate general linear model was built with A allele as a fixed factor (in a dominant model, because of low number in the AA group, see Table 1), gender, age, lifetime depression, MADRS and neuroticism as covariates, and PAL memory score, PAL errors and PAL required trials as the dependent variables. Wilks' Lambda of the A allele showed $F = 5.661; P = 0.001$. The A allele exerted a nominally significant effect on each PAL variable in the model (PAL memory: $F = 15.159; P < 0.001$; PAL errors: $F = 9.350; P = 0.003$; PAL required trials: $F = 8.546; P = 0.004$). Another multivariate general linear model was built with the A allele as a fixed factor (in a dominant model), gender, age, lifetime depression, current depression (MADRS) and neuroticism as covariates, and SOC ITT and SOC correct trial rate as dependent variables. For Wilks' Lambda of the A allele, $F = 1.665; P = 0.192$. In this model, the A allele did not exert a significant effect on any of the SOC variables (SOC ITT: $F = 0.612; P = 0.435$; SOC correct trial rate: $F = 2.039; P = 0.155$; Figure 2).

DISCUSSION

In our study in a large general sample ATP6V1B2 rs1106634 A allele was a significant risk factor for lifetime major depression but was not associated with current depressive symptom manifestation. This risk effect of the A allele on depression was only partially mediated by neuroticism, a well-known risk factor for depression, which was associated with both depression and the A allele in our study indicating overlapping genetic risk but different mechanisms. Furthermore, our results show that rs1106634 may exert a brain region-specific effect independently of lifetime history or current level of depression impacting temporal-hippocampal but not frontal functions as reflected by significantly decreased performance in A allele carriers on the PAL but not on the SOC neurocognitive test. Our results thus show that ATP6V1B2 rs1106634 may play an important role in the long-term development and risk for depression, but not in its cross-sectional symptomatology, possibly via its effect on hippocampal function conceived to play a central role in depression.

Association of rs1106634 with lifetime risk of depression is not mediated by neuroticism

The rs1106634 A allele was significantly associated with neuroticism, a well-established prospective risk factor for depression. Neuroticism is a personality trait of negative emotionality associated with less adaptive coping with inner and outer stressors and increased mood lability leading to a heightened risk of experiencing anxiety and depressed mood. Therefore, its presence is likely to play a developmental role in depression, which further supports our notion that the A allele influences long-term adjustment and trait-like risk factors rather than state-like symptomatic presentation of depression. Although neuroticism is one of the most widely studied endophenotypes of depression with about 55% of shared genetic risk, we found that neuroticism only partially mediated the effects of rs1106634 on lifetime depression. We conclude that rs1106634 may influence neuroticism and depression in ways that are partially independent.

Association of rs1106634 with hippocampal but not prefrontal neurocognitive dysfunction

In our study, rs1106634 A allele was associated with hippocampal cognitive deficits indicated by decreased performance on all measures of the PAL task independently of lifetime or current depression and neuroticism, while prefrontal functions indicated by the SOC test remained intact. Thus our results raise the possibility that the effect of this polymorphism is area-specific affecting temporal rather than prefrontal lobe function. Given the role of the vacuolar ATPase in cellular function and the fact that the hippocampus is an area with high energy and oxygen need and increased vulnerability compared with other regions, it is possible that this area is more sensitive to possible functional consequences of this polymorphic variant.

PAL performance involves learning random visuospatial associations and is sensitive to hippocampal damage. Michopoulos et al. reported that impaired PAL was associated with measures of the severity and chronicity of depression including illness duration and number of prior episodes. In contrast in the same study no such measures of depression chronicity were found to be associated with SOC scores. This is in line with our assumption that rs1106634 effects are reflected in lifetime rather than acute depression measures and are linked to long-term risk and development of depression.

Our results indicating a specific association between hippocampal dysfunction and rs1106634 are especially interesting as hippocampal dysfunction is thought to play a central role as part of a larger dysregulated circuitry implicated in the pathophysiology of depression. Loss of hippocampal volume is associated with several measures of increased long-term depression severity and worse clinical outcome and structural effects of genetic influences. The hippocampus is considered a brain region with increased sensitivity to stress, resulting in structural changes as well as enhanced vulnerability to metabolic insults and depression is also a highly stress-associated illness. Therefore, the possible consequences of genetically determined differences in vacuolar H^+ATPase may be especially manifested in the most

Figure 2. Multivariate general linear models indicate a significant effect of ATP6V1B2 rs1106634 genotype on PAL task performance but not on SOC task performance. Multivariate general linear models for the three PAL variables (a) and the two SOC variables (b) with gender, age and lifetime depression, current (MADRS) depression and neuroticism as covariates. Means of standardized residuals for the PAL (a) and SOC (b) variables are displayed in function of ATP6V1B2 rs1106634 genotype. A allele carriers show a significantly lower memory score on the first trial (P < 0.001), but a significantly higher total number of errors (P = 0.003) and required trials (P = 0.004) than those with GG genotype in the PAL task (a). However, the two genotype groups (A allele carriers and GG carriers) do not differ in the two aspects of SOC performance (SOC ITT P = 0.435, SOC correct trial rate P = 0.155) (b), PAL, paired associates learning task; PAL errors, total number of errors on PAL; PAL memory score, memory score on the first trial of PAL; PAL required trials, total number of trials on PAL; SOC, Stockings of Cambridge task; SOC correct trial rate, rate of problems solved in minimum moves; SOC ITT, mean of all initial thinking times throughout the SOC task. Means (and the s.e.m.) of standardized residuals for the three PAL (a) and the two SOC (b) scores, partialling out variance accounted for by gender, age, lifetime depression, MADRS and neuroticism, are represented according to genotype.
Vulnerable regions such as the hippocampus in high stress-associated illnesses such as depression.

Possible mechanisms behind the role of rs1106634 in depression and hippocampal dysfunction

Rs1106634 is located in the intron of the ATP6V1B2 gene, encoding the B subunit of the ATP-catalytic site containing the V1 cytosolic domain of the vacuolar proton pump-ATPase,11 which mediates acidification of various eukaryotic intracellular organelles such as lysosomes and endosomes, necessary for processes including protein sorting, receptor-mediated endocytosis and synaptic vesicle proton-gradient generation. The protonmotive force generated by vacuolar ATPases is used for various secondary reactions including synaptic vesicle reuptake, accumulation and storage.36,37 Transport including retrieval and reemployment of synaptic vesicles is an essential component in the management and maintenance of neurotransmission. The vacuolar H+ATPase plays a key role in the energization of regenerated synaptic vesicles after endocytosis, and thus in providing power for the replenishment of neurotransmitters via specific vesicular transporters.37,38 Therefore generation of the electrochemical H+ gradient is essential and even its minor or partial disturbance may cause altered quantal neurotransmitter release.36,39 Vacular ATPase inhibition was found to cause downregulation in important signaling pathways including Wnt and Notch, although it has not yet been clarified to what extent this effect is a consequence of its function in endosome acidification or whether it is due to its effect on endocytosis and trafficking.40 Vacular ATPase was also found to maintain neural stem cells in the developing cortex of mice.41 Although the role of vacuolar ATPase in central nervous system function is becoming clearer, no specific effect of this polymorphism on neuronal function has been specifically investigated.

One possible mechanism by which variations in the vacuolar ATPase may exert their effect on depression risk is its role in oxidative stress, also implicated in the etiopathology of depression. Emotional stressors appear to induce inflammatory responses which are in turn associated with increased proinflammatory cytokine production, stimulating reactive oxygen and nitrogen species production and leading to oxidative and nitrosative stress, free radical production and brain damage by increasing neurodegeneration and impairing neurogenesis.41 Chronic inflammation as well as oxidative and nitrosative stress has long been hypothesized to play a role in recurrent major depression and especially in neurocognitive deficits.31,41 Cellular redox status may play a role in the regulation of the vacuolar H+ATPase hypothesized to be a redox sensor regulating neurotransmitter storage in response to growth factor signaling or oxidative stress, leading to decreased neurotransmitter amounts in vesicles and therefore decreased or diminished neurotransmitter release.42 In a more recent GWAS, a suggestive association between serum myeloperoxidase levels and a region on chromosome 8p21.3 containing ATP6V1B2 genes was reported.43 Myeloperoxidase is a surrogate marker of prooxidative stress in major depression, and its serum levels were previously associated with depression.44 Myeloperoxidase expression was also reported to be associated with neurodegeneration, higher risk of Alzheimer’s disease,45 neuronal cell death and neurogenesis inhibition.46

The brain shows enhanced vulnerability to oxidative damage as it uses large amounts of oxygen. Lipids, including unsaturated fatty acids, which are especially reactive with free radicals are abundant in central nervous system cells. Furthermore, several brain regions are high in metal ions that promote reactive oxygen species formation, and lower antioxidant concentrations are observable in the brain compared with other body organs.41 The most sensitive to oxidative damage in the central nervous system are, among others, CA1 and CA4 hippocampal regions as well as the dorsal lateral striatum and III and V cortex layers.31 Especially CA1 neurons are highly vulnerable, playing a role in long-term memory and spatially related tasks,30 which corresponds to the deficit seen in our study.

In silico functional analysis of rs1106634 and comparison with results of the Psychiatric Genetic Consortium GWAS

In silico functional prediction using the SNP Function Prediction Tool (http://snpsinfo.niehs.nih.gov/snpsinfo/snpfunc.htm) showed no functional effects of our investigated SNP rs1106634, however, a nearby SNP with an LD of 0.62, namely rs1042426, is a microRNA binding site, which suggests that this genetic region may have functional consequences related to gene expression regulation. Furthermore, the latest mega-analysis of the Psychiatric Genetic Consortium demonstrated that SNPs in high LD (based on the CEU population data) with rs1106634, namely rs6586899 (r² = 0.96) and rs4335136 (r² = 0.86), showed nominally significant associations with major depressive disorder (rs6586899 P = 0.004, rs4335136 P = 0.017), while the functional rs1042426 has a trend effect (P = 0.089) supporting the weak but replicable role of ATP6V1B2 in lifetime depression.36

Limitations

Several limitations of our study must be noted. We measured depressive symptoms and neurocognitive performance cross-sectionally. Both current and lifetime depression was based on self-report thus could be influenced by reporting and recalling bias. Recent life events possibly influencing current depression as well as general intellectual performance possibly impacting neurocognitive performance were not included in our models. Furthermore, our study sample is a general, non-epidemiological and non-representative population sample based on volunteers, therefore may be subject to sampling bias especially with respect to depression.

Conclusion and implication for further studies

The main finding of our study is supporting the role of the ATP6V1B2 rs1106634 A allele, implicated in depression GWAS-s with a suggestive significance, as a risk allele for lifetime but not current depression suggesting a role in the long-term development of affective illness. This finding is further underlined by the association of this SNP with neuroticism, a well-established risk factor of depression, while the fact that neuroticism only partially mediated the association between rs1106634 and depression indicates a differential involvement of rs1106634 in these two phenomena. Our results also show that the effect of rs1106634 on lifetime risk of depression may be due to the association of the A allele with hippocampal dysfunction, thought to play a central role in the development of depression. We must also mention that while rs1106634 was implicated in several GWAS-s in psychiatric patients, it was not among the 15 genetic loci identified in major depression in a most recent study using an extremely large cohort with less intensive phenotyping approach using self-reported lifetime depression,10 the same phenotype as used in our study. On the clinical level, our findings concerning the role of the vacuolar ATPase in depression and depression-associated cognitive deficits suggest that pharmacological interventions targeting this molecule may be promising new molecular agents in the treatment of depression in general and also in cases with more marked neurocognitive symptoms, also possibly able to tackle the progressive and degenerative nature of such symptoms. Our results thus emphasize the importance of looking beyond the monoaminergic systems in investigating mechanisms underlying depression in order to establish a more accurate model of this illness and pinpoint possible targets for pharmacological intervention, and also stress the importance of investigating

Translational Psychiatry (2016), 1 – 8
polymorphisms implicated in depression GWASs, even if only with a weak effect, with respect to their possible role and mechanism.

CONFLICT OF INTEREST
JFWD variously performed consultancy, speaking engagements and research for Bristol-Myers Squibb, AstraZeneca, Eli Lilly, Schering Plough, Janssen-Cilag and Servier (all fees are paid to the University of Manchester to reimburse them for the time taken); he also has share options in P1vital. MLA received consultancy fees from Alkermes, Lundbeck-Otsuka Ltd, Janssen-Cilag Ltd. The remaining authors declare no conflict of interest.

ACKNOWLEDGMENTS
The study was supported by the Sixth Framework Program of the European Union, NewMood, LSHM-CT-2004-503474; the TAMPOR-4.2.1.B-09/1-KMR-2010-0001; by the Bulgarian Brain Research Program (Grant No. KITB_NAP-A-II/14) and National Development Agency (Grant No. KITB_NAP, 13-1-2013-0001); the Hungarian Academy of Sciences (MTA-SE Neuropsychopharmacology and Neuropsychology Research Group); and by the MTA-SE-NAP B Genetic Brain Imaging Migraine Research Group, Hungarian Academy of Sciences, Semmelweis University (Grant No. KITB_NAP, 13-2-2015-0001). KG is a recipient of the Bolyai Scholarship of the Hungarian Academy of Sciences. The funders had no role in study design, data collection and analysis, and interpretation of the data, decision to publish or preparation of the manuscript. We thank Diana Chase, Emma J Thomas, Darragh Downey, Kathryn Lloyd-Williams, Zoltan G Toth for their assistance in the recruitment and data acquisition; Hazel Platt for her assistance in genotyping; Heaton Mersey Medical Practice and Cheddale Medical Practice for their assistance in the recruitment.
