Aerodynamic Model for Tandem Flapping Wings

A. H. M. Faisal* and A. Filippone†

University of Manchester, Manchester M13 9PL, United Kingdom

Abstract

An aerodynamic model for tandem flapping wings is proposed. The model attempts to represent insects such as the dragonfly. Two advances are presented: the aerodynamic model with tandem wings flapping simultaneously, and the wing stroke optimization. The aerodynamic model accounts for the inflow effects of the front wing (fore-wing) on the rear wing (hind-wing). The stroke is optimized at two flight conditions (acceleration and level flight) by using a heuristic optimization procedure (particle swarming). The vector of the design variables consists of 28 independent parameters (14 per wing), each with a constrained range derived from the maximum available power, the flight muscle ratio and kinematics of real insects. The cost function is the propulsive efficiency coupled with constraints for flight stability. Prediction of the level flight efficiency is in agreement with the flight muscle efficiency. The maximum acceleration is found to be dependent on the size of the flight muscle. Finally, a study of the wing shape is presented for both level and accelerating flight conditions.

Nomenclature

a_u	= wing relative acceleration, y -axis
a_v	= wing relative acceleration, z -axis
b_t	= wing thickness
$c(r)$	= wing chord
$c(\hat{r})$	= normalized chord
$\bar{c}$	= mean chord length
C_d	= drag coefficient
$C_d(0)$	= drag coefficient at $\alpha = 0$ degree
$C_d(\pi/2)$	= drag coefficient at $\alpha = 90$ degrees
C_l	= lift coefficient
C_r	= wing rotational lift coefficient
C_t	= wing translational lift coefficient
C_y	= horizontal force coefficient
C_z	= vertical force coefficient
C_η	= rate of the wing rotation
dr	= wing section
dt	= time step
D	= drag
f	= frequency (motion frequency)

h	= hind-wing

I Introduction

At present there is considerable interest in the physics of flight at very small scale. This interest is a mix of fascination with insect flight and the technology drive to design smaller and smaller flying platforms. Nature-inspired flight is one of the avenues being explored. For example, the dragonfly can routinely accelerate with a $3g$ rate to a speed of 10 m/s on its own body muscles^{1;2}, and is capable of generating an instantaneous lift five times greater than its weight³. Each of its wings can be actuated independently^{2;4}; this allows greater maneuverability at a fraction of the energy required by other insects of comparable mass⁵. Marden⁶ recorded that the flight-muscle growth of the dragonfly is approximately double its body mass during adult maturation.

Most of the research on dragonflies has focused on flight characteristics^{1;5;6} and its relation to the wing configuration^{7;8;9}. There are studies on the kinematic variations^{4;10} and the flow interaction^{11;12;13}. The study of Wang & Russell¹⁴ on the effect of the fore- and hind-wing interactions has shown that the dragonfly would use minimum power to generate the required force in hovering flight. Lehmann¹⁵ published a study of the wing-wake interaction of wings in tandem configuration and contended that the aerodynamic efficiency can be enhanced by recovering energy from the wake. A further review of tandem and biplane wings was shown by Platzner *et al.*¹⁶, where the authors observe that biplane configurations are not present in nature, possibly due to poor efficiency in hover flight.

Aerodynamic models for tandem wings are somewhat limited by the computing times required.

Since the flapping wing can be regarded as a case of moving boundary problem, body-fitted or unstructured-grid methods are employed in computational fluid dynamic solutions¹⁷. The experimental work of Warkenting & DeLaurier¹⁸, inspired by the dragonfly, included a parametric study of various flapping tandem configurations without parameter optimization, and concluded that asymmetric flapping is inefficient. However, the experiments highlight the fact that the large number of degrees of freedom needs exploring with rational methods.

This paper contributes a low-order aerodynamic model that is able to couple both fore- and hind-wing together and to account for the interaction of the flow, particularly the fact that the hind-wing operates in the slipstream of the fore-wing. We introduce an aerodynamic model expanded from an earlier contribution¹⁹ whilst retaining a reduced level of computational cost.

The estimation of the optimum kinematic parameters for the wing is obtained via a particle swarm optimization²⁰. Each of the design variables is subjected to a constrained range derived from experimental studies of the dragonfly^{5;6;21}. The cost function of the optimization is the propulsive efficiency coupled with constraints for flight stability.

II Wing Aerodynamic Model

This section describes the mathematical model for fore- and hind-wing in multiple wing design configuration. Since this method is fully described in a previous paper¹⁹, only a brief explanation of the method is presented, along with the developments arising from the tandem-wing configuration.

A Wing Geometry

An elliptical function (tear-drop shape) is used for the fore- and hind-wing shape:

$$c(r) = \frac{4\bar{c}}{\pi} \sqrt{1 - \frac{r^2}{R^2}} \quad (1)$$

where $\bar{c}$ is the mean chord length, R is the wing length, and r is the radial distance measured from the root to the wing tip. The reference chords and spans (radii) of the wings are given in Table 1.

Table 1: *Mean chord length $\bar{c}$ and wing length R of the dragonfly fore- and hind wing.*

	$\bar{c}$ (mm)	R (mm)
Fore-Wing	5.88	27.85
Hind-Wing	7.68	26.90

In order to have the closest similarity to an insect wing (real wing shape), a set of polynomials is used to approximate the dragonfly wing planform. The new equation is derived from the analysis of the digital photograph shown in Fig. 1.

Figure 1: *Dragonfly wing. The thick solid line represents the wing derived from Eq. 2.*

$$c(\hat{r}) = a + b\hat{r} + c\hat{r}^2 + d\hat{r}^3 + e\hat{r}^4 + f\hat{r}^5 \quad (2)$$

where $c(\hat{r})$ is the normalized chord and $\hat{r}$ is the normalized wing span. For each wing, the polynomial coefficients are grouped into two sections, representing the upper and lower part of the wings, respectively. The corresponding coefficients for each part of the wing sections are given in Table 2.

Table 2: *Coefficients of the polynomial Eq. 2.*

	<i>Fore-Wing</i>		<i>Hind-Wing</i>	
	<i>Upper</i>	<i>Lower</i>	<i>Upper</i>	<i>Lower</i>
<i>a</i>	0.0154	-0.0273	0.0321	-0.0144

<i>f</i>	-4.0250	-1.8304	-3.7509	-0.7086

B Wing Kinematics

A parametrized kinematics model is applied in describing the fore- and hind wing motions²². There are three angular movements: weaving ϕ , back and forward in the horizontal plane; flapping θ in the vertical plane; pitching η is the rotating angle about a span-wise axis (axis lies at mid-section of the chord). These angles are calculated from

$$\phi(t) = \frac{\phi_m}{\sin^{-1}(K)} \sin^{-1} [K \sin(2\pi ft + \Phi_\phi)] + \phi_0 \quad (3)$$

$$\theta(t) = \theta_m \cos(2\pi Nft + \Phi_\theta) + \theta_0 \quad (4)$$

$$\eta(t) = \frac{\eta_m}{\tanh(C_\eta)} \tanh \left[C_\eta \sin(2\pi ft + \Phi_\eta) \right] + \eta_0 \quad (5)$$

C Coordinate Definitions and Transformation

The wing is assumed to move freely as a thin rigid flat plate pinned at the root, with the flapping kinematics realized by rotations about a fixed joint. The rotation and the translation of fore- (subscript f) and hind wing (subscript h) are calculated using a rotation matrix

$$(\mathbf{R})_{\langle f, h \rangle} = (\mathbf{R}_\beta)_{\langle f, h \rangle} (\mathbf{R}_\theta)_{\langle f, h \rangle} (\mathbf{R}_\phi)_{\langle f, h \rangle} (\mathbf{R}_\eta)_{\langle f, h \rangle} \quad (6)$$

where

$$\begin{aligned} \mathbf{R}_\beta &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \beta & \sin \beta \\ 0 & -\sin \beta & \cos \beta \end{pmatrix}, \quad \mathbf{R}_\theta = \begin{pmatrix} \cos \theta & 0 & -\sin \theta \\ 0 & 1 & 0 \\ \sin \theta & 0 & \cos \theta \end{pmatrix} \\ \mathbf{R}_\phi &= \begin{pmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathbf{R}_\eta = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \eta & -\sin \eta \\ 0 & \sin \eta & \cos \eta \end{pmatrix} \end{aligned} \quad (7)$$

The local position of the fore- and hind-wing from the earth axes (subscript e) to the blade element axes (subscript η) can be transformed via a rotation matrix

$$\mathbf{p}_{\eta \langle f, h \rangle} = (\mathbf{R})_{\langle f, h \rangle} \mathbf{p}_{e \langle f, h \rangle} \quad (8)$$

The local velocity of the wing can be evaluated numerically using a finite difference approximation of Eq. (8) at times t and $t + \Delta t$ over a period T .

$$\begin{cases} F_{iner,y} = \int_0^R \left(\frac{c(r)}{\bar{c}R} m_w \right) v \dot{\eta} dr \\ F_{iner,z} = - \int_0^R \left(\frac{c(r)}{\bar{c}R} m_w \right) u \dot{\eta} dr \end{cases} \quad (11)$$

$$\begin{cases} F_{AM,y} = \int_0^R (m_{22}v\dot{\eta} - m_{11}a_u) dr \\ F_{AM,z} = - \int_0^R (m_{11}u\dot{\eta} - m_{22}a_v) dr \end{cases} \quad (12)$$

$$\begin{cases} F_{Vis,y} = - \int_0^R \frac{1}{2} \rho c(r) [C_d(0) \cos^2(\alpha) + C_d(\pi/2) \sin^2(\alpha)] (\sqrt{u^2 + v^2}) u dr \\ F_{Vis,z} = - \int_0^R \frac{1}{2} \rho c(r) [C_d(0) \cos^2(\alpha) + C_d(\pi/2) \sin^2(\alpha)] (\sqrt{u^2 + v^2}) v dr \end{cases} \quad (13)$$

with the circulation Γ , the added mass terms m_{11} , m_{22} and the wing inertia I_a defined by

$$\Gamma = -\frac{1}{2}C_t \left(\sqrt{u^2 + v^2} \right) \sin 2\alpha c(r) + \frac{1}{2}C_r \dot{\eta} c^2(r) \quad (14)$$

$$m_{11} = \frac{1}{4}\pi\rho b_t^2 \quad \text{and} \quad m_{22} = \frac{1}{4}\pi\rho c^2(r) \quad \text{and} \quad I_a = \frac{1}{128}\pi\rho (c^2(r) + b_t^2)^2 \quad (15)$$

where u and a_u and v and a_v are the y -axis and z -axis local velocity and acceleration component on the η reference frame. The density of the fluid is $\rho = 1.225 \text{ kg/m}^3$; the mass is $m = 121.9 \times 10^{-6} \text{ kg}$; the aerodynamic coefficients are taken from Berman & Wang²² and Usherwood & Ellington²³, as given in Table 3.

Table 3: *Aerodynamic coefficients of the dragonfly fore- and hind-wing.*

	$C_d(0)$	$C_d(\pi/2)$	C_r
Fore-Wing	0.12	2.71	π
Hind-Wing	0.14	2.85	π

The lift due to the wing translation C_t is calculated via the extended lifting line theory, adapted from Taha *et al.*²⁴.

The force is transformed from the η reference system back to the earth reference system by multiplication of Eq. (9) with the inverse matrix $(\mathbf{R}^{-1})_{\langle f,h \rangle}$

$$(\mathbf{F}_e)_{\langle f,h \rangle} = (\mathbf{R}^{-1})_{\langle f,h \rangle} (\mathbf{F}_w)_{\langle f,h \rangle} \quad (16)$$

Thus, the net lift to weight ratio L/W from fore- and hind-wing can be determined from

$$\frac{L}{W} = \frac{N_w [(F_{e,z})_f + (F_{e,z})_h]}{m g} \quad (17)$$

where N_w is the number of wings, and $g = 9.81 \text{ m/s}^2$ is the acceleration of gravity. By multiplying the respective forces with their moment-arms, the moments (M_x, M_y, M_z) are obtained. The power due to aerodynamic and inertia effects can be determined by multiplying the respective moments with the angular rotations ($\Omega_\eta, \Omega_\theta$ and Ω_ϕ)

$$\begin{cases} P_{aero} = N_w \oint |M_x \Omega_\eta + M_y \Omega_\theta + M_z \Omega_\phi|_{aero} \\ P_{iner} = N_w \oint |M_x \Omega_\eta + M_y \Omega_\theta + M_z \Omega_\phi|_{iner} \end{cases} \quad (18)$$

Finally, the total power resultant from both fore- and hind-wing is

$$P = (P_{aero} + P_{iner})_f + (P_{aero} + P_{iner})_h \quad (19)$$

E Induced Velocity

The interaction between the fore-wing on the hind-wing is modeled via some induction factors, as shown in Fig. 3. The inflow angle of the fore-wing is estimated from

$$\psi_f = \tan^{-1} \left(\frac{v_f}{u_f} \right) = \tan^{-1} \frac{v_z (1 + a_f)}{v_y (1 - a'_f)} \quad (20)$$

The hind-wing is affected by the inflow of the fore-wing. The inflow component v_z of the hind-wing is multiplied by the axial induced flow factor of the fore-wing according to the following equation:

$$\psi_h = \tan^{-1} \left(\frac{v_h}{u_h} \right) = \tan^{-1} \frac{[v_z (1 + a_f)] (1 + a_h)}{v_y (1 - a'_h)} \quad (21)$$

where u and v of both wings are the local velocity components on the ϕ reference frame calculated from $\mathbf{V}_\phi = \mathbf{R}_\phi \mathbf{R}_\theta \mathbf{R}_\beta \mathbf{V}_e$.

The flow of the fore-wing extends downstream and enters the area of influence (or actuator disk) of the hind-wing. It is assumed that the air approaching the hind-wing already has a portion of the fore-wing velocity in the z direction, normal to the stroke plane. This assumption is similar to the experimental results of Gravish *et al.*²⁵, in which the resultant airflow from a pair of wings working together is higher than the total air flow from individual contributions. The axial (a) and radial (a') induction factors are calculated as shown in Ref.¹⁹.

Figure 3: Flow interaction due to the slipstream (induced flow) of the fore-wing on the hind-wing.

F Stroke Optimization

The optimization of the wing kinematics is carried out with the particle swarming optimization²⁰. Here, the chosen cost function are maximum propulsive efficiency for level flight and maximum acceleration for accelerating flight; with constraints on the flight stability, muscular power ratio⁵, flight muscle ratio⁶, and wing kinematics²¹.

Table 4: Range (or constraints) for the optimal model parameters.

Parameter	Fore-Wing	Hind-Wing
f	30.0 - 45.00 Hz	30.0 - 45.00 Hz
ϕ_m	30.0° - 60.0°	30.0° - 60.0°
θ_m	1.0° - 20.0°	1.0° - 20.0°
η_m	1.0° - 90.0°	1.0° - 90.0°
ϕ_o	-30.0° - 30.0°	-30.0° - 30.0°
θ_o	5.0° - 30.0°	-30.0° - -5.0°
η_o	-90.0° - 90.0°	-90.0° - 90.0°
Φ_ϕ	-180.0° - 180.0°	-180.0° - 180.0°
Φ_θ	-180.0° - 180.0°	-180.0° - 180.0°
Φ_η	-180.0° - 180.0°	-180.0° - 180.0°
K	0.01 - 1.00	0.01 - 1.00
N	1 or 2	1 or 2
C_η	0.01 - 5.00	0.01 - 5.00
β_m	5.0° - 30.0°	5.0° - 30.0°

In level flight, the lift is equal to the weight ($L = W$) and the thrust is equal to the drag ($T = D$). In accelerated flight, the lift and thrust are greater than the weight ($L > W$) and the drag ($T > D$), respectively. The range for the model parameters of the wing kinematics is given in

Table 4, following the observation range of data from the experiment by Wakeling & Ellington²¹.

Furthermore, as to comply with the physical power of the real insect, the available power has to be limited²⁶. Following Marden⁶ and Wakeling & Ellington²⁷, the maximum flight muscle ratio m_{muscle}/m and the available muscular power ratio P/m_{muscle} can be assumed equal to 60% and 150 W/kg, respectively. Hence, by equating these two values, the available power P/m is estimated to be at a maximum of 90 W/kg.

G Flight Performance

The level flight efficiency η_{level} can be determined from the relation between the amount of thrust T and power P required,

$$\eta_{level} = \frac{TV}{P} \quad (22)$$

In order to simulate vertically accelerating flight, the sum of the vertical force produced from both wings (fore- and hind-wing) must be greater than the weight. Similarly, the horizontal component of the thrust has to be greater than the drag to accelerate the insect horizontally. The excess vertical and horizontal forces, F_v and F_h , respectively, can be computed from

$$F_v = (L_f + L_h) - W \quad (23)$$

$$F_h = D_f + D_h \quad (24)$$

where L_f , L_h and D_f , D_h are the lift and drag forces generated by the fore- and hind-wing, respectively. For convenience, the acceleration is presented in terms of g force. The non-dimensional vertical and horizontal specific excess forces are:

$$\bar{F}_v = \frac{F_v}{W} \quad (25)$$

$$\bar{F}_h = \frac{F_h}{W} \quad (26)$$

Finally, the attainable specific excess forces $\bar{F}_a$ produced can be formulated as

$$\bar{F}_a^2 = \bar{F}_v^2 + \bar{F}_h^2 \quad (27)$$

III Results and Discussion

We present the results of tandem flapping wings in level and accelerating flight; we include the analysis of the wing kinematics and the wing shapes on each flight mode.

A Level Flight

The flight speed range is based on the speed of dragonflies observed by Wakeling & Ellington²¹, ranging from 0.25 m/s up to 2 m/s, with an increment of 0.25 m/s.

Figure 4: *Thrust ratio, mean angle of attack and stroke plane angle of dragonfly in level flight mode.*

Figure 4 shows the thrust ratio, mean angle of attack and stroke plane angle of dragonfly in level flight mode (the optimization is applied at each value of V). The mean angle of attack is calculated based on the average value of both wings over a full flapping period. From this figure, it shows that the wing stroke plane angle increases with the flight speed, whilst the thrust and the wing mean angle of attack are reduced. This reduction in thrust is as indicated by Mazaheri & Ebrahimi²⁸. The changes in these wing angles are consistent with those measured by Azuma & Watanabe⁵ and Wakeling & Ellington²¹. With a lower angle of attack, the amount of thrust required to overcome the drag would be lower.

From Fig. 5, the power is reduced to a minimum when the flight speed is 1.5 m/s. This is similar to the results presented by May¹ and Azuma & Watanabe⁵, which was predicted the minimum power to be at a speed between 1 and 2 m/s. The relationship between the power and the kinematics of the wing could give the best logical correlation in describing the changes of power over the range

Figure 5: *Power ratio, frequency and weaving angle of dragonfly in level flight mode.*

of flight speed. The results indicate that the frequency f and the weaving angle ϕ_m at each speed follow the trend of the predicted power.

Figure 6: *Flight efficiency of dragonfly in level flight mode.*

As shown in Fig. 6, the maximum flight efficiency in level flight is predicted to reach 12.7% at $V = 1.5$ m/s. This is in agreement with the flight muscle efficiency measured by Wakeling & Ellington²⁷; these authors provided estimates of $\sim 13\%$ on the basis of measurements of the thoracic temperature elevation and the thermal conductance of the thorax.

B Accelerated Flight

In this section, an analysis is conducted to predict the dragonfly's maximum acceleration. This is to assess claims (Ref. ^{1;2;3}) that the dragonfly would be able to generate an enormous amount of force that can be used for accelerating in such high-speed flight manoeuvres (e.g. take-off or in escape). It is known that the size of the flight muscle is relative to the size, maturation, and species of the insect^{6;29}. Here we simulate the maximum acceleration with flight muscle ranging from 30% to 60%; this equates to power-to-weight ratio between 50 W/kg and 90 W/kg.

Figure 7: Vertical and horizontal specific excess forces corresponding to the available power.

Figure 7 shows a logical correlation that the vertical and horizontal specific excess forces are increasing with the amount of available power. The vertical specific excess force is 10 to 20% higher than the horizontal specific excess force for a given power-to-weight ratio. The lowest vertical and horizontal specific excess forces are at $P/W = 50$ W/kg with $\bar{F}_v \sim 2.7$ and $\bar{F}_h \sim 2.4$, and reaching the highest at $P/W = 90$ W/kg with $\bar{F}_v \sim 4.4$ and $\bar{F}_h \sim 3.5$.

Figure 8 shows the maximum attainable acceleration increases with the amount of prescribed available power. The predicted g force has a minimum of ~ 3.6 and maximum of ~ 5.6 at $P/W = 50$ W/kg and $P/W = 90$ W/kg, respectively. These values are comparable to the measurements reported in the literature³.

Figure 8: Maximum attainable acceleration corresponding to the amount of available power.

C Wing Kinematic Analysis

An analysis of the wing kinematics for level and accelerating flight modes is shown to validate the model with real insect wing kinematics^{2;4;21}. The fore- and hind-wing tip paths relative to the wing base for level and accelerating flights are presented in Fig. 9 and Fig. 10, respectively.

Figure 11 and Fig. 12 show the wing kinematics for the two flight modes. In this analysis, we selected the wing kinematics at $V = 1.25$ m/s for the level flight and at $P/W = 60$ W/kg accelerating flight.

Figure 11(a) indicates that the fore- and hind-wing flap out-of-phase in level flight. The largest phase difference is measured at $V = 2$ m/s, at which point the hind-wing leads the fore-wing by ~ 30 degrees. However, as shown in Fig. 11(b) for the accelerating flight, the wings flap in-phase.

Figure 11(c) illustrates the changes in phase for level and accelerating flight modes. These results are in agreement with observations made by Ruppel² & Alexander⁴, who reported that the dragonfly flap its wings in-phase to generate higher propulsive forces. Tandem flapping wings have optimal phase patterns depending on the flight condition, which is also in agreement with the results presented by Diana³⁰.

The pitching angles of fore- and hind-wings in the two flight modes are illustrated in Fig. 12. This figure shows that the magnitude of the pitching angle are different for these two modes, with lower pitching amplitude in level flight (η_1) than in accelerating flight (η_2), as illustrated in Fig. 12(c). However, the changes of the pitch angle η on each stroke for both flight modes are found

Figure 9: *Simulated wingtip paths relative to the wing base for level flight. The axes are normalized to wing length.*

Figure 10: *Simulated wingtip paths relative to the wing base for accelerating flight. The axes are normalized to the wing length.*

the same; both start with lower η during the first half-stroke (or down-stroke), $0 < \text{cycle} < 0.5$. This is because during the down-stroke the wing moves in the direction of the flight and provides higher lift. During the upstroke the inflow is reduced. In this instance, a larger pitch angle is required to compensate for the reduction of the relative inflow. The changes in angle of attack and the relative velocity during down-stroke and upstroke are illustrated in Fig. 13. The changes in the wing kinematics (ϕ and η) are in line with experimental studies^{9;31;32}.

Figure 11: *Simulated weaving angle of fore- and hind-wing in two flight modes.*

D Wing Shape Analysis

Furthering from the analysis of the tear-drop wing shape, a comparison of flight performance in level and accelerating flight between the tear-drop and real wing is presented; the wings have equal area and wing span. The kinematics of both wings is optimized for maximum propulsive efficiency in level flight, and maximum acceleration for an accelerating flight. The tear-drop and real wing shapes are illustrated in Fig. 14.

Figure 15: *Flight efficiency with two wing shapes.*

Figure 15 shows that the level flight efficiency of the real wing shape is higher than the tear-drop wing shape over the range of speeds. With the upper limit increases of up to $\sim 12\%$ at 2.0 m/s. The efficiency of the real and the tear-drop peaks at $V = 1.50$ m/s. The magnitude of acceleration with the real wing is slightly higher than that of the tear-drop wing over the range of available

power, Fig. 16. This is attributed to a larger chord on the mid-section, as shown in Fig. 14.

IV Conclusions

An aerodynamic propulsion model has been developed for tandem flapping wings. Our aim was to study the propulsive characteristics in level and accelerated flight of an insect-size vehicle. The model proposed accounts for flow interference between fore- and hind wing. Inflow corrections have been introduced in the direction normal to the stroke plane. The propulsion model was coupled with an independent numerical optimization capable of handling multiple-parameters disjoint search spaces. The stroke optimization was demonstrated for cases with 28 independent parameters.

The changes in power at each flight speed can be correlated with the changes of the wing kinematics. The predicted level flight efficiency is in agreement with the experimental results of flight muscle efficiency. The maximum attainable acceleration is found to increase with the size of the flight muscle (or power available).

Through the analysis of the wing kinematics, it is shown that the wings will flap out-of-phase to fly efficiently in level flight. However, to obtain maximum acceleration, the wings flap in phase. This result is in agreement with observations of dragonflies in nature.

A separate analysis addressed the role of different wing shapes (tear-drop and dragonfly wing planforms). The results indicate that the real wing shape has better propulsive efficiency and acceleration than the tear-drop wing. Interdependencies between the flapping kinematics, the wing shape and the wing structure have strong influence on the optimal stroke.

Acknowledgments

The authors would like to acknowledge the Ministry of Higher Education Malaysia (MOHE) and Universiti Putra Malaysia (UPM) for offering the PhD scholarship for Faisal AHM under the academic training scheme (SLAI).
