Abstract

Background
Burn wounds cause high levels of morbidity and mortality worldwide. People with burns are particularly vulnerable to infections; over 75% of all burn deaths (after initial resuscitation) result from infection. Antiseptics are topical agents that act to prevent growth of micro-organisms. A wide range are used with the intention of preventing infection and promoting healing of burn wounds.

Objectives
To assess the effects and safety of antiseptics for the treatment of burns in any care setting.

Search methods
In September 2016 we searched the Cochrane Wounds Specialised Register, the Cochrane Central Register of Controlled Trials (CENTRAL), Ovid MEDLINE, Ovid MEDLINE (In-Process & Other Non-Indexed Citations), Ovid Embase, and EBSCO CINAHL. We also searched three clinical trials registries and references of included studies and relevant systematic reviews.
There were no restrictions based on language, date of publication or study setting.

**Selection criteria**
We included randomised controlled trials (RCTs) that enrolled people with any burn wound and assessed the use of a topical treatment with antiseptic properties.

**Data collection and analysis**
Two review authors independently performed study selection, risk of bias assessment and data extraction.

**Main results**
We included 56 RCTs with 5807 randomised participants. Almost all trials had poorly reported methodology, meaning that it is unclear whether they were at high risk of bias. In many cases the primary review outcomes, wound healing and infection, were not reported, or were reported incompletely.

Most trials enrolled people with recent burns, described as second-degree and less than 40% of total body surface area; most participants were adults. Antiseptic agents assessed were: silver-based, honey, Aloe Vera, iodine-based, chlorhexidine or polyhexanide (biguanides), sodium hypochlorite, merbromin, ethacridine lactate, cerium nitrate and *Ameba courna*. Most studies compared antiseptic with a topical antibiotic, primarily silver sulfadiazine (SSD); others compared antiseptic with a non-antibacterial treatment or another antiseptic. Most evidence was assessed as low or very low certainty, often because of imprecision resulting from few participants, low event rates, or both, often in single studies.

**Antiseptics versus topical antibiotics**
Compared with the topical antibiotic, SSD, there is low certainty evidence that, on average, there is no clear difference in the hazard of healing (chance of healing over time), between silver-based antiseptics and SSD (HR 1.25, 95% CI 0.94 to 1.67; $I^2 = 0$%; 3 studies; 259 participants); silver-based antiseptics may, on average, increase the number of healing events over 21 or 28 days' follow-up (RR 1.17 95% CI 1.00 to 1.37; $I^2 = 45$%; 5 studies; 408 participants) and may, on average, reduce mean time to healing (difference in means -3.33 days; 95% CI -4.96 to -1.70; $I^2 = 87$%; 10 studies; 979 participants).

There is moderate certainty evidence that, on average, burns treated with honey are probably more likely to heal over time compared with topical antibiotics (HR 2.45, 95% CI 1.71 to 3.52; $I^2 = 66$%; 5 studies; 140 participants).

There is low certainty evidence from single trials that sodium hypochlorite may, on average, slightly reduce mean time to healing compared with SSD (difference in means -2.10 days, 95% CI -3.87 to -0.33, 10 participants (20 burns)) as may merbromin compared with zinc sulfadiazine (difference in means -3.48 days, 95% CI -6.85 to -0.11, 50 relevant participants). Other comparisons with low or very low certainty evidence did not find clear differences between groups.

Most comparisons did not report data on infection. Based on the available data we cannot be certain if antiseptic treatments increase or reduce the risk of infection compared with topical antibiotics (very low certainty evidence).

**Antiseptics versus non-antibacterial comparators**
We found high certainty evidence that treating burns with honey, on average, reduced mean times to healing in comparison with non-antibacterial treatments (difference in means -5.3 days, 95% CI -6.30 to -4.34; $I^2 = 71$%; 4 studies; 1156 participants) but this comparison included some unconventional treatments such as amniotic membrane and potato peel. There is moderate certainty evidence that honey probably also increases the likelihood of wounds healing over time compared to unconventional anti-bacterial treatments (HR 2.86, 95% CI 1.60 to 5.11; $I^2 = 50$%; 2 studies; 154 participants).

There is moderate certainty evidence that, on average, burns treated with nanocrystalline silver dressings probably have a slightly shorter mean time to healing than those treated with Vaseline gauze (difference in means -3.49 days, 95% CI -4.46 to -2.52; $I^2 = 0$%; 2 studies, 204 participants), but low certainty evidence that there may be little or no difference in numbers of healing events at 14 days between burns treated with silver xenograft or paraffin gauze (RR 1.13, 95% CI 0.59 to 2.16 1 study; 32 participants). Other comparisons represented low or very low certainty evidence.

It is uncertain whether infection rates in burns treated with either silver-based antiseptics or honey differ compared with non-antimicrobial treatments (very low certainty evidence). There is probably no difference in infection rates between an iodine-based treatment compared with moist exposed burn ointment (moderate certainty evidence). It is also uncertain whether infection rates differ for SSD plus cerium nitrate, compared with SSD alone (low certainty evidence).

**Mortality**
Mortality was low where reported. Most comparisons provided low certainty evidence that there may be little or no difference between many treatments. There may be fewer deaths in groups treated with cerium nitrate plus SSD compared with SSD alone (RR 0.22, 95% CI 0.05 to 0.99; $I^2 = 0$%, 2 studies, 214 participants) (low certainty evidence).

**Authors' conclusions**
It was often uncertain whether antiseptics were associated with any difference in healing, infections, or other outcomes. Where there is moderate or high certainty evidence, decision makers need to consider the applicability of the evidence from the comparison to their patients. Reporting was poor, to the extent that we are not confident that most trials are free from risk of bias.
Antiseptics for Burns

Review question

We reviewed the evidence about whether antiseptics are safe and effective for treating burn wounds.

Background

Burn wounds cause many injuries and deaths worldwide. People with burn wounds are especially vulnerable to infections. Antiseptics prevent the growth of micro-organisms such as bacteria. They can be applied to burn wounds in dressings or washes, which may help to prevent infection and encourage wound healing. We wanted to find out if antiseptics are more effective than other types of treatment, or whether one antiseptic may be more effective than others, in reducing infection and speeding up healing.

Study characteristics

In September 2016 we searched for randomised controlled trials (RCTs) involving antiseptic treatments for burn wounds. We included 56 studies with 5807 participants. Most participants were adults with recent second-degree burns taking up less than 40% of their total body surface area. The antiseptics used included: silver-based, honey, iodine-based, chlorhexidine or polyhexanide (biguanides). Most studies compared antiseptics with a topical antibiotic (applied to the skin). A smaller number of studies compared antiseptics with a non-antibacterial treatment, or with another antiseptic.

Key results

The majority of studies compared antiseptic treatments with silver sulfadiazine (SSD), a topical antibiotic used commonly in the treatment of burns. There is low certainty evidence that some antiseptics may speed up average times to healing compared with SSD. There is also moderate certainty evidence that burns treated with honey probably heal more quickly compared with those treated with topical antibiotics. Most other comparisons did not show a clear difference between antiseptics and antibiotics.

There is evidence that burns treated with honey heal more quickly (high certainty evidence) and are more likely to heal (moderate certainty evidence) compared with those given a range of non-antibacterial treatments, some of which were unconventional. Burns treated with antiseptics such as nanocrystalline silver or merbromin may heal more quickly on average than those treated with Vaseline gauze or other non-antibacterial treatments (moderate or low certainty evidence). Comparisons of two different antiseptics were limited but average time to healing may be slightly quicker for wounds treated with povidone iodine compared with chlorhexidine (low certainty evidence). Few participants in the studies experienced serious side effects, but this was not always reported. The results do not allow us to be certain about differences in infection rates. Mortality was low where reported.

Quality of the evidence

Most studies were not well reported and this makes it difficult to be sure if they were at risk of bias. In many cases a single (often small) study provides all the evidence for the comparative effects of the different treatments; and some similar studies provided conflicting results. Where there is moderate or high certainty evidence clinicians will need to consider whether the evidence from the comparison is relevant to their patients.

This plain language summary is up to date as of September 2016.

Background

Description of the condition

A burn can be defined as an injury to the skin or other organic tissue caused by thermal trauma (Hendon 2002). Burns are caused by heat (including contact with flames, high temperature solids (contact burns) and liquids (scalds)), chemicals, electricity, friction or abrasion, and radiation (including sunburn and radioactivity). Respiratory damage, as a consequence of smoke inhalation, is also considered a type of burn (Hendon 2002).

Incidence and impact

Burn injuries are a considerable source of morbidity and mortality (Mock 2008). As outlined by the World Health Organization (WHO), the burden of injury falls predominantly on people living in low- and middle-income countries; over 95% of the 300,000 annual deaths from fires occur in these countries (Mock 2008). Total burn mortality is inversely correlated with both national income and income inequality (Peck 2013). The much greater number of injuries resulting in disability and disfigurement are also disproportionately concentrated in low- and middle- income countries (Mock 2008 ). Fire-related burns have been estimated to account for 10 million lost disability-adjusted life years (DALYs) every year (WHO 2002), a figure that does not include the social and personal impact of non-disabling disfigurement. Additional mortality and morbidity are caused by other types of burns including scalding, and electrical and chemical burns (American Burn Association 2013). Globally, children and young people, and women are disproportionately affected by burn injuries, while the types and causes of injury in children differ somewhat from those seen in adults (Peck 2012).

Although, both incidence of burns and associated morbidity and mortality are much lower in high-income countries, they are nevertheless significant. Annually in the UK around 250,000 people suffer a burn; 175,000 attend a hospital emergency department with a burn and, of these, approximately 13,000 are admitted to hospital and 300 die (National Burn
Care Review 2001). In the USA, the figures for those receiving medical treatment were 450,000 with 40,000 hospitalisations and 3400 deaths (American Burn Association 2013). These data indicated that, in contrast to the global pattern, a majority of people with burns were male (69%), and while children aged under five years accounted for 20% of all cases, 12% were people aged 60 years or older (American Burn Association 2013).

**Burn severity and extent**

The severity of burns is categorised by the depth of the tissues affected; in the case of burns to the skin, this is the layers of cells in the skin (Demling 2005). Epidermal burns (sometimes known as first-degree burns) are confined to the epidermis (outer surface of the skin), are not usually significant injuries, and heal rapidly and spontaneously. Partial-thickness burns (sometimes known as second-degree burns) involve varying amounts of the dermis (skin) and may become deeper and heal with varying amounts of scarring, which will be determined partly by the depth of the burn. Partial-thickness burns are divided into superficial and deep partial-thickness wounds: superficial partial-thickness burns extend into the papillary or superficial upper layer of the dermis, whilst deep partial-thickness burns extend downward into the reticular (lower) layer of the dermis. Full-thickness burns (sometimes known as third-degree burns) extend through all the layers of the skin. Where full-thickness burns extend beneath the skin layers, into underlying structures (fat, muscle, bone); they are sometimes called full-thickness and/or fourth-degree burns (Demling 2005; European Practice Guidelines 2002).

The age of people with burns affects their prognosis, with infants and older people having poorer outcomes (Alp 2012; DeSanti 2005). The area of a burn will also be key to the time taken to heal, and also to the risk of infection (Alp 2012). Burn size is determined by the percentage of the total body surface area that is burned; estimating this can be difficult, particularly in children; the most accurate method uses the Lund and Browder chart (Hettiaratchy 2004).

The depth of burn and its location may be predictors of psychological, social, and physical functioning following treatment (Baker 1996). Most extensive burns are a mixture of different depths, and burn depth can change and increase in the acute phase after the initial injury; the extent to which this occurs will depend on the effectiveness of the initial treatment (resuscitation) (Hettiaratchy 2004).

**Burn wound infection**

Infections are a potentially serious complication in people with burns. US data indicated that over a 10-year period more than 19,000 complications in people with burns were reported. While 31% of these were recorded as pulmonary complications, 17% were wound infections, or cellulitis, or both, and 15% were recorded as sepsicaemia (a serious, life-threatening illness caused by bacteria in the bloodstream) or other infectious complications (Latenser 2007). We were unable to locate other large-scale international data for infection-related complication rates.

Up to 75% of all burn deaths following initial resuscitation are a consequence of infection rather than more proximal causes such as osmotic shock and hypovolaemia (types of changes in the concentration of fluids in the body) (Bang 2002; Fitzwater 2003). Although this figure includes other types of hospital/healthcare-acquired infections such as pneumonia, a substantial proportion follow an infection which would meet accepted criteria for infections of burn wounds (Alp 2012; Peck 1998). Burn wound infections also contribute to morbidity, lengthening recovery times, and increasing the extent of scarring (Church 2006; Oncul 2009), as well as the pain experienced by people with burns (Tengvall 2006).

All open wounds offer an ideal environment for microbial colonisation. Most wounds will contain some micro-organisms but this will not necessarily lead to adverse events (AWMA 2011). Recently the view has developed that it is infection with sufficient or specific types of pathogenic micro-organisms, or both, and possibly resulting biofilms (Percival 2004; Wolcott 2008) that may lead to negative outcomes and, potentially, delayed healing (Bowler 2003; Davies 2007; Madsen 1996; Tengvall 1996). Biofilms are formed by bacteria that grow on a surface to form a film of cells. Growing in this way can make them more resistant to bactericidal agents. Previously it was thought that the critical factor was a threshold concentration of microbes (bioburden) (Robson 1968). However, the impact of microbial colonisation on wound healing is not independent of the host response. The ability of the host to provide adequate immune response is likely to be as critical, if not more so, in determining whether a wound becomes infected as the specifics of the flora in the wound.

People with burns have a particular vulnerability to infection, as a result of the loss of the physical barrier to infection, and the reduction in immunity mediated by the lost cells (Ninnemann 1992; Winkelstein 1984). Infections commonly occur in the acute period following the burn (Church 2006).

The spectrum of infective agents that can be present in the burn wounds varies. Nowadays, Gram-positive bacteria such as Staphylococcus aureus (S. aureus), and Gram-negative bacteria such as Pseudomonas aeruginosa (P. aeruginosa) are the predominant pathogens (Wibbenmeyer 2006), although other micro-organisms such as fungi, yeasts, and viruses can also be present (Church 2006; Polavarapu 2008). Multidrug-resistant micro-organisms, such as methicillin-resistant S. aureus (MRSA), are frequently and increasingly identified in burns (Church 2006; DeSanti 2005; Keen 2010).

**Description of the intervention**

**Standard care**

The care for burn wounds is determined in part by their severity (depth), area, and location (National Network for Burn Care 2012). For significant injuries involving the lower layers of skin, standard care may involve a range of dressings or skin substitutes, or both, (Wasiak 2013) and more complex interventions such as hyperbaric oxygen therapy and negative pressure wound therapy (Dumville 2012; Villanueva 2004). The nature and extent of the burn wound, together
with the type and amount of colonising micro-organisms can also influence the risk of invasive infection (Bang 2002; Fitzwater 2003).

Antiseptics

Antiseptics are topical antimicrobial agents which are thought to prevent the growth of pathogenic micro-organisms without damaging living tissue (Macpherson 2004). Applications broadly fall into two categories: lotions used for wound irrigation or cleaning, or both, with a brief contact time (unless used as a pack/soak), and products that are in prolonged contact with the wound such as creams, ointments, and impregnated dressings (BNF 2016).

Agents used primarily for wound irrigation/cleaning across wound types are commonly based on povidone-iodine, chlorhexidine and peroxide agents. Less commonly used are traditional agents such as gentian violet and hypochlorites. Longer contact creams and ointments include fusidic acid, mupirocin, neomycin sulphate and iodine (often as cadexomer iodine). Some of these are rarely used in clinical practice. Silver-based products such as silver sulfadiazine and silver-impregnated dressings are increasingly used, as are honey-based products. Aloe Vera is also sometimes used as an antiseptic although there is currently no available sterile source.

The British National Formulary (BNF) categorises antimicrobial dressings under honey-based, iodine-based, silver-based, and other, which includes dressings impregnated with agents such as chlorhexidine or peroxides (BNF 2016). The choice of dressing for a burn wound is based on a number of factors including the need to accommodate movement, the minimisation of adherence to the wound surface, the prevention of infection, the ability to absorb wound fluid and maintain humidity, and the active promotion of healing (Wasiak 2013).

Antibiotics are substances that destroy or inhibit the growth of bacteria (Macpherson 2004) (normally by inhibiting deoxyribonucleic acid (DNA), protein synthesis or by disrupting the bacterial cell wall). Routine prophylaxis against infection with systemic antibiotics is not currently recommended. While it may reduce burn wound infections, or colonisation, or both, it does not decrease mortality, and may in fact increase the risk of selecting resistant micro-organisms such as MRSA (Avni 2010; Barajas-Nava 2013).

In contrast, antiseptics (the focus of this review) can be bactericidal (in that they kill micro-organisms) or they can work by slowing the growth of organisms (bacteriostatic) (Macpherson 2004), but they usually work without damaging living tissue. Antiseptics can reduce the presence of other micro-organisms such as viruses and fungi, as well as bacteria, and often work by damaging the surface of microbes (Macpherson 2004). According to the BNF (BNF 2016) antiseptics are used to reduce the presence of micro-organisms on living tissue.

How the intervention might work

This review considers the use of antiseptics for both clinically infected and non-infected burn wounds. The rationale for treating clinically infected wounds with antiseptic agents is to kill or slow the growth of the pathogenic micro-organisms, thus preventing an infection from worsening and spreading (Kingsley 2004). In the case of burns, the prevention of infections, and systemic infections in particular, is especially important, as people with burns can have lowered immunity as a consequence of their injury (Church 2006). Improved healing may also result, although evidence on the association between wound healing and infection is limited (Jull 2015; O’Meara 2001; Storm-Versloot 2010).

There is a widely held view that wounds that do not have clear signs of clinical infection, but that have characteristics such as retarded healing, may also benefit from a reduction in bacterial load (bioburden). Again, evidence for this is limited (AWMA 2011; Howell-Jones 2005).

Why it is important to do this review

Burn wounds are a source of substantial morbidity and mortality; much of this results from the original wound becoming infected (Latenser 2007). While infections pose real risks to people with burns, the problem of antibiotic and multi-drug resistance in bacteria continues to grow (Church 2006; DeSanti 2005; Keen 2010); alternatives to routine use of antibiotics for the minimisation of infection can be a key element of care.

There is a current published Cochrane review of antibiotics for the prevention (prophylaxis) of burn wound infection (Barajas-Nava 2013), while a second Cochrane review of antibiotics for the treatment of infected burn wounds is now underway (Lu 2016). This review of antiseptics complements these reviews and will complete the assessment of evidence for agents with antimicrobial properties in the care of all burn wounds, whether infected or not. There will be some overlap between this review and other Cochrane and non-Cochrane reviews of dressings for partial-thickness burns (Wasiak 2013), and of individual agents with antiseptic properties for all types of wounds (Aziz 2012; Jull 2015; Storm-Versloot 2010). However, this review will provide a single synthesis of the randomised evidence relating to all antiseptics for any type of burn wound.

Objectives

To assess the effects and safety of antiseptics for the treatment of burns in any care setting.

Methods

Criteria for considering studies for this review

Types of studies

We included published and unpublished randomised controlled trials (RCTs), including cluster-RCTs, irrespective of
language of report. We planned to only include crossover trials if they reported outcome data at the end of the first treatment period, prior to crossover. We excluded quasi-randomised studies.

**Types of participants**
We included studies enrolling participants of any age with burn wounds. We included burns of any type, severity, extent or current infection status, managed in any care setting. We accepted authors’ definitions of the category of burn represented in included trials. We included trials of participants with burns, alongside people with other types of wounds where the participants with burns constituted at least 75% of the trial population.

**Types of interventions**
The interventions of interest were topical antiseptic agents. We included any RCT in which the use of a specific topical antiseptic was the only systematic difference between treatment groups; where the antiseptic agent was an integral part of the dressing we allowed for this. Control regimens could have included placebo, an alternative antiseptic, another therapy such as antibiotics or isolation of the patient, standard care or no treatment. We included studies that evaluated intervention schedules, including other therapies, provided that these treatments were delivered in a standardised way across the trial arms. We excluded trials in which the presence or absence of a specific antiseptic was not the only systematic difference. We also excluded evaluations of antiseptics used to prepare for the surgical treatment of burns (i.e. where antisepsis is part of the perioperative procedure).

We anticipated that likely comparisons would include use of different antiseptic agents, in particular, the use of different types of dressings impregnated with antiseptic agents; comparisons of impregnated dressings or other antiseptic preparations with standard care; and comparison of antiseptics with topical or systemic antibiotics. We anticipated that other elements of standard care may have been co-interventions across trial arms.

**Types of outcome measures**

**Primary outcomes**
The primary effectiveness outcome for this review was wound healing. Trialists use a range of different methods of measuring and reporting this outcome. We considered that RCTs that reported one or more of the following provided the most relevant and rigorous measures of wound healing:

- time to complete wound healing (correctly analysed using survival, time-to-event approaches). Ideally the outcome would be adjusted for appropriate covariates e.g. baseline wound area/degree/duration;
- proportion of wounds completely healed during follow-up (frequency of complete healing).

We used and reported the study authors’ definitions of complete wound healing where this was available. We reported outcome measures at the latest time point available (assumed to be length of follow-up if not specified) and the time point specified in the methods as being of primary interest (if this was different from latest time point available).

Where both the outcomes above were reported, we presented all data in a summary outcome table for reference, but focused on reporting time to healing. When time to healing was analysed as a continuous measure, but it was not clear whether all wounds healed, we documented the use of the outcome in the study, but we did not extract, summarise or use the data in any meta-analysis.

The primary safety outcome for the review was change in wound infection status (as defined by the study authors). In the case of wounds that were considered to be clinically infected at baseline, we assessed resolution of infections. In the case of wounds that were not considered to be clinically infected at baseline, we assessed the incidence of new infections. We also assessed the incidence of septicaemia, where data permitted. We did not extract data on microbiological assays not clearly linked to a diagnosis of infection.

**Secondary outcomes**
We included the following secondary outcomes:

- Adverse events
  - Where reported, we extracted data on all serious adverse events and all non-serious adverse events. We did not report individual types of adverse events other than pain (see below) or infection (see **Primary outcomes**).
- Health-related quality of life
  - We included quality of life where it was reported, using a validated scale such as the SF-36 or EQ-5D, or a validated disease-specific questionnaire. Ideally, reported data were adjusted for the baseline score.
- Pain (including pain at dressing change)
  - We included pain only where mean scores with a standard deviation were reported using a scale validated for the assessment of pain levels, such as a visual analogue scale (VAS).
- Resource use (when presented as a mean with standard deviation)
  - We included measures of resource use such as number of dressing changes, number of nurse visits, length of hospital stay, and need for other interventions.
- Costs associated with resource use (including estimates of cost-effectiveness)
- Mortality (overall and infection-related).

**Search methods for identification of studies**

**Electronic searches**
We searched the following electronic databases to identify relevant RCTs:
- the Cochrane Wounds Specialised Register (searched 26 September 2016);
- the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library, 2016, Issue 8, searched 26 September 2016);
- Ovid MEDLINE (1946 to 26 September 2016);
- Ovid MEDLINE (In-Process & Other Non-Indexed Citations) (searched 26 September 2016);
- Ovid Embase (1974 to 26 September 2016);
- EBSCO Cumulative Index to Nursing and Allied Health Literature (CINAHL) (1982 to 28 September 2016)

The search strategies are shown in Appendix 1.

We combined the Ovid MEDLINE search with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision) (Lefebvre 2011). We combined the Embase search with the Ovid Embase filter developed by the UK Cochrane Centre (Lefebvre 2011). We combined the CINAHL searches with the trial filters developed by the Scottish Intercollegiate Guidelines Network (SIGN 2015). There were no restrictions with respect to language, date of publication or study setting.

We also searched the following clinical trials registries.
- ClinicalTrials.gov (www.clinicaltrials.gov/).
- WHO International Clinical Trials Registry Platform (apps.who.int/trialsearch/Default.aspx).
- EU Clinical Trials Register (www.clinicaltrialsregister.eu/).

Searching other resources
We tried to identify other potentially eligible trials or ancillary publications by searching the reference lists of retrieved included trials, as well as relevant systematic reviews, meta-analyses and health technology assessment reports.

Data collection and analysis
Selection of studies
Two review authors independently assessed the titles and abstracts of the citations retrieved by the searches for relevance. After this initial assessment, we obtained full-text copies of all studies considered to be potentially relevant. Two review authors independently checked the full papers for eligibility; we resolved disagreements by discussion and, where required, the input of a third review author. We obtained translation support, where necessary, for non-English language reports. Where the eligibility of a study was unclear, we attempted to contact study authors. We recorded all reasons for exclusion of studies for which we had obtained full copies. We completed a PRISMA flowchart to summarise this process (Liberati 2009).

Where studies were reported in multiple publications/reports, we attempted to obtain all publications. Whilst we included each study only once in the review, we extracted data from all reports to ensure that we obtained all available relevant data.

Data extraction and management
We extracted and summarised details of the eligible studies. Where possible we extracted data by treatment group for the prespecified interventions and outcomes in this review. Two review authors independently extracted data; discrepancies were resolved through discussion or by consultation with a third reviewer. Where data were missing from reports, we attempted to contact the study authors and request this information.

Where we included a study with more than two intervention arms, we only extracted data from intervention and control groups that met the eligibility criteria. Where the reported baseline data related to all participants, rather than to those in relevant treatment arms, we extracted the data for the whole trial and noted this. We collected outcome data for relevant time points as described in the Types of outcome measures.

Where possible, we extracted the following data:
- bibliographic data, including date of completion/publication;
- country of origin;
- unit of randomisation (participant/wound);
- unit of analysis;
- trial design e.g. parallel, cluster;
- care setting;
- number of participants randomised to each trial arm and number included in final analysis;
- eligibility criteria and key baseline participant data including cause, depth, extent (area/proportion of total body surface area (TBSA)) and location of burns; ages of participants, and whether they had a diagnosis of infection at baseline;
- details of treatment regimen received by each group;
- duration of treatment;
- details of any co-interventions;
- primary and secondary outcome(s) (with definitions and, where applicable, time points);
- outcome data for primary and secondary outcomes (by group);
- duration of follow-up;
- number of withdrawals (by group) and number of withdrawals (by group) due to adverse events;
- publication status of study;
• source of funding for trial.

Assessment of risk of bias in included studies

Two review authors independently assessed included studies using the Cochrane tool for assessing risk of bias (Higgins 2011a). This tool addresses specific domains: sequence generation, allocation concealment, blinding, incomplete data, selective outcome reporting and other issues. In this review we recorded issues with unit of analysis, for example where a cluster trial has been undertaken but analysed at the individual level in the study report.

We assessed blinding of outcome assessment and completeness of outcome data for each of the review outcomes separately. We presented our assessment of risk of bias using two 'Risk of bias' summary figures; one is a summary of bias for each item across all studies, and a second shows a cross-tabulation of each trial by all of the risk of bias items.

We summarised a study’s risk of selection bias, detection bias, attrition bias, reporting bias and other bias. In many of the comparisons included in this review, we anticipated that blinding of participants and personnel may not be possible. For this reason the assessment of the risk of detection bias focused on whether blinded outcome assessment was reported (because wound healing can be a subjective outcome, it can be at high risk of measurement bias when outcome assessment is not blinded). For trials using cluster randomisation, we also planned to consider risk of bias for recruitment bias, baseline imbalance, loss of clusters, incorrect analysis and comparability with individually-randomised trials (Higgins 2011b) (Appendix 3).

Measures of treatment effect

We reported time-to-event data (e.g. time-to-complete wound healing) as hazard ratios (HRs) when possible, in accordance with the methods described in the Cochrane Handbook for Systematic Reviews of Interventions (Deeks 2011). If studies reporting time-to-event data (e.g. time to healing) did not report an HR, then, when feasible, we estimated this using other reported outcomes, such as numbers of events, through the application of available statistical methods (Parmar 1998; Tierney 2007). This included deriving an HR from data reported for multiple time points, where at least three time points were reported. Where no HR could be calculated, we reported dichotomous data at the latest time point. For dichotomous outcomes, we calculated the risk ratio (RR) with 95% confidence intervals (CIs). For continuous outcome data, we used the difference in means (MD) with 95% CIs for trials that used the same assessment scale. When trials used different assessment scales, we used the standardised difference in means (SMD) with 95% CIs.

Unit of analysis issues

Where studies were randomised at the participant level and outcomes measured at the wound level, for example for wound healing, we treated the participant as the unit of analysis when the number of wounds assessed appeared to be equal to the number of participants (e.g. one wound per person).

One unit of analysis issue that we anticipated was that randomisation may have been carried out at the participant level, with the allocated treatment used on multiple wounds per participant (or perhaps only on some participants), but data were presented and analysed per wound (clustered data).

In cases where included studies contained some or all clustered data, we reported this, noting whether data had been (incorrectly) treated as independent. We recorded this as part of the 'Risk of bias' assessment.

We also included studies with the split-body design where either people with two similar burn wounds were enrolled and each burn wound was randomised to one of the interventions, or where one half of a wound was randomised to one treatment and the other half to a different treatment. These approaches are similar to the 'split-mouth' approach (Lesaffre 2009). These studies should be analysed using paired data which reflects the reduced variation in evaluating different treatments on the same person. However, it was often not clear whether such analysis had been undertaken. This lack of clarity is noted in the 'Risk of bias' assessment and in the notes in the Characteristics of included studies table.

We adopted a pragmatic but conservative post-hoc approach to analyses including clustered and paired data. We included such studies in meta-analyses where possible (where unadjusted clustered data would produce too-narrow CIs and unadjusted paired data too-wide CIs). We undertook a post-hoc sensitivity analysis to explore the impact of including data that had been inappropriately unadjusted. Where the sensitivity analysis produced a materially different result to the primary analysis, we used this as the basis for the GRADE assessment and the 'Summary of findings' table. Where we pooled studies with paired data with one other trial, we also reported the results of both trials individually, and where a paired data study was the sole trial reporting outcome data, we noted the issues related to its design. We also noted where these trials were included in meta-analyses but did not contribute weight to the analyses due to zero events or lack of measures of variance.

Dealing with missing data

It is common to have data missing from trial reports. Excluding participants from the analysis post randomisation, or ignoring participants who are lost to follow-up compromises the randomisation and potentially introduces bias into the trial. If it was thought that study authors might be able to provide some missing data, we attempted to contact them; however, data are often missing because of loss to follow-up. In individual studies, when data on the proportion of burns healed were presented, we assumed that randomly-assigned participants not included in an analysis had an unhealed wound at the end of the follow-up period (i.e. they were considered in the denominator but not in the numerator). When a trial did not specify participant group numbers before dropout, we presented only complete case data. For time-to-healing analysis using survival analysis methods, dropouts should be accounted for as censored data. Hence all participants will be contributing to the analysis. We acknowledge that such analysis assumes that dropouts are missing at random and there is no pattern of
missingness. We presented data for all secondary outcomes as a complete case analysis.

For continuous variables (e.g. length of hospital stay) and for all secondary outcomes, we presented available data from the study reports/study authors and did not impute missing data. Where measures of variance were missing, we calculated these, wherever possible (Higgins 2011a). If calculation was not possible, we contacted the study authors. Where these measures of variation remained unavailable and we could not calculate them, we excluded the study from any relevant meta-analyses that we conducted.

**Assessment of heterogeneity**

Assessment of heterogeneity can be a complex, multi-faceted process. Firstly, we considered clinical and methodological heterogeneity; that is the degree to which the included studies varied in terms of participants, interventions, outcomes, and characteristics such as length of follow-up. We supplemented this assessment of clinical and methodological heterogeneity by information regarding statistical heterogeneity - assessed using the Chi² test (we considered a significance level of P < 0.10 to indicate statistically significant heterogeneity) in conjunction with the I² statistic (Higgins 2003). I² examines the percentage of total variation across RCTs that is due to heterogeneity rather than chance (Higgins 2003). Very broadly, we considered that I² values of 25%, or less, may mean a low level of heterogeneity (Higgins 2003), and values of 75% or more, indicated very high heterogeneity (Deeks 2011). Where there was evidence of high heterogeneity, we attempted to explore this further (see Data synthesis).

**Assessment of reporting biases**

Reporting biases arise when the dissemination of research findings is influenced by the nature and direction of results. Publication bias is one of a number of possible causes of 'small study effects', that is, a tendency for estimates of the intervention effect to be more beneficial in smaller RCTs. Funnel plots allow a visual assessment of whether small study effects may be present in a meta-analysis. A funnel plot is a simple scatter plot of the intervention effect estimates from individual RCTs against some measure of each trial’s size or precision (Sterne 2011). Funnel plots are only informative when there are a substantial number of studies included in an analysis; we had planned to present funnel plots for meta-analyses that included at least 10 RCTs using Review Manager 5 (RevMan 5) (RevMan 2014) but there were no analyses with sufficient studies.

**Data synthesis**

We combined details of included studies in narrative review according to the comparison between intervention and comparator, the population and the time point of the outcome measurement. We considered clinical and methodological heterogeneity and undertook pooling when studies appeared appropriately similar in terms of burn type and severity, intervention type and antibacterial agent, duration of treatment and outcome assessment.

In terms of a meta-analytical approach, in the presence of clinical heterogeneity (review author judgement), or evidence of statistical heterogeneity, or both, we used a random-effects model. We planned to only use a fixed-effect approach when clinical heterogeneity was thought to be minimal and statistical heterogeneity was estimated as non-statistically significant for the Chi² value and 0% for the I² assessment (Kontopantelis 2013). We adopted this approach as it is recognised that statistical assessments can miss potentially important between-study heterogeneity in small samples, hence the preference for the more conservative random-effects model (Kontopantelis 2012). Where clinical heterogeneity was thought to be acceptable, or of interest, we considered conducting meta-analysis even when statistical heterogeneity was high, but attempted to interpret the causes behind this heterogeneity and considered using meta-regression for that purpose, if possible (Thompson 1999; Thompson 2002).

We presented data using forest plots, where possible. For dichotomous outcomes we presented the summary estimate as a RR with 95% CIs. Where continuous outcomes were measured in the same way across studies, we planned to present a pooled MD with 95% CIs; we pooled SMD estimates where studies measured the same outcome using different methods. For time-to-event data, we plotted (and, where appropriate, pooled) estimates of HRs and 95% CIs, as presented in the study reports, using the generic inverse variance method in RevMan 5 (RevMan 2014). Where time to healing was analysed as a continuous measure, but it was not clear if all wounds healed, we documented use of the outcome in the study, but did not summarise the data or use the data in any meta-analysis.

**Summary of findings' tables**

We presented the main results of the review in 'Summary of findings' tables. These tables present key information concerning the quality of the evidence, the magnitude of the effects of the interventions examined and the sum of available data for the main outcomes (Schünemann 2011a). The 'Summary of findings' tables also include an overall grading of the evidence related to each of the main outcomes using the GRADE approach. The GRADE approach defines the ‘certainty’ of a body of evidence as the extent to which one can be confident that an estimate of effect or association is close to the true quantity of specific interest. The certainty of a body of evidence involves consideration of within-trial risk of bias (methodological quality), directness of evidence, heterogeneity, precision of effect estimates and risk of publication bias (Schünemann 2011b). We presented the following outcomes in the 'Summary of findings' tables:

- time-to-complete wound healing, when analysed using appropriate survival analysis methods;
- proportion of wounds completely healing during the trial period;
- mean time to healing when all wounds healed;
- changes in clinical infection status;
- adverse events.
Where comparisons had limited available data for specified outcomes we did not generate a 'Summary of findings' table for this comparison. Instead we decided to present these data together with GRADE judgements in an additional table, in order to keep the 'Summary of findings' tables section of the review manageable and improve readability.

In terms of the GRADE assessment, when making decisions for the risk of bias domain we downgraded only when studies had been classed at high risk of bias for one or more domains. We did not downgrade for unclear risk of bias assessments. In assessing the precision of effect estimates we assessed the size of confidence intervals, downgrading twice for imprecision when there were very few events and CIs around effects included both appreciable benefit and appreciable harm. We considered CI to be especially fragile where there were fewer than 50 participants; event rates were also considered in determining fragility.

Subgroup analysis and investigation of heterogeneity

When possible, we planned to perform subgroup analyses to explore the effect of interventions in children under the age of 18, in adults, and in older adults (aged over 65 years). When possible, we also planned to use subgroup analyses to assess the influence of burn size and depth on effect size. If there had been sufficient data these analyses would have assessed whether there were differences in effect sizes for burns of different depths.

When possible, we planned to perform subgroup analyses to explore the influence of risk of bias on effect size. We planned to assess the influence of removing from meta-analyses studies classified as having high and unclear risk of bias. These analyses would have only included studies that were assessed as having low risk of bias in all key domains, namely, adequate generation of the randomisation sequence, adequate allocation concealment, and blinding of outcome assessor for the estimates of treatment effect.

Elements of this Methods section are based on the standard Cochrane Wounds protocol template.

Results

Description of studies

Results of the search

The search identified a total of 1565 records after duplicates were removed, of which we assessed 214 records as full texts (Figure 1).

Included studies

We included 56 studies reported in 66 publications, with a total of 5807 randomised participants. Most studies had two intervention groups but two studies had three arms, each study evaluating two relevant comparisons (Chen 2008; Thomas 1995), one study had four arms and evaluated five relevant comparisons (Li 1994) and one (Piccolo-Daher 1990) had five arms and evaluated two relevant comparisons. A number of the studies enrolled participants with two comparable burn wounds and randomly assigned the wounds to the interventions (that is randomisation was at the wound rather than participant level).

Included studies assessed the following types of comparisons.

- Comparisons between antiseptics and topical antibiotics
- Comparisons between two antiseptics
- Comparisons between antiseptics and treatments without antimicrobial properties.

The main groups of interventions and the direct comparisons between them are shown in Figure 2 and listed in Table 1.

Studies awaiting classification

Five studies are awaiting classification (Gao 2016; Liu 2016; Rege 1999; Santi 2013; Wang 2015). We have been unable to obtain the full publication for Rege 1999 despite international search requests. Gao 2016 and Santi 2013 are published in abstract only and there is insufficient information available from these; we have so far been unable to contact the authors. Liu 2016 and Wang 2015 are very recent Chinese language studies for which we are awaiting both the full texts and a translation. See Studies awaiting classification for more details.

Excluded studies

We excluded 136 studies reported in 143 records after appraisal as full texts. We ordered many of these because the initial record contained so little information that it was not immediately obvious that they were not relevant. Upon obtaining the full texts it was clear that many studies were not eligible. More nuanced reasons for exclusion were noted for 29 studies reported in 32 records (see Characteristics of excluded studies). Eight trials were quasi-randomised (Babb 1977; Bowser 1981; Cason 1966; Choudhary 2013; Daryabeigi 2010; Helvig 1979; Mohammadi 2013; Zhu 2006); eight assessed a comparison where use of an antiseptic was not the only difference between the groups (Afilalo 1992; Ang 2002; Ang 2003; Fisher 1968; Kumar 2004; Shoma 2010; Subrahmanyam 1999; Weng 2009); one assessed a mixture of antiseptic and non-antiseptic agents within the same intervention group (Chokotho 2005); four assessed the same antiseptic in each arm (Brown 2016; Gee Kee 2015; Tredget 1998; Verbelin 2014) three assessed a population with a minority of people with burns (Colombo 1993; Madhusudhan 2015; Subrahmanyam 1993a), while three evaluated post-surgical burns patients (Chmyrev 2011; Palombo 2011; Vehmeyer-Heeman 2005); two trials were not designed to evaluate clinical efficacy, effectiveness or safety of interventions (Chen 2007; Xu 2009). We also identified one paper which was found to be a non-randomised extension of an included study (Inman 1984); this is listed as an additional
No studies had a low risk of bias for all domains. We judged only one study (Tang 2015) to be at low risk of bias across all except one domain, where there was an unclear risk of bias. All other studies had an unclear or high risk of bias for two or more domains. There were 17 studies with one domain classed at high risk of bias and we rated three of these studies as being at high risk of bias in more than one domain. Most studies had multiple domains which were at an unclear risk of bias. For only two domains (attrition bias and reporting bias) did we consider a majority of the studies to be at low risk of bias. Figure 3 and Figure 4 illustrate the predominance of unclear judgements across the domains.

Allocation (selection bias)

Generation of randomisation sequence and concealment of allocation were not well reported. Most studies had an unclear risk of bias with allocation concealment, especially, poorly documented.

Incomplete outcome data (attrition bias)

Most studies were at low risk of attrition bias with all participants accounted for or only a small number missing from analyses. Approximately 10% of studies were at high risk of bias and 20% were unclear.

Selective reporting (reporting bias)

Just over half the studies were at low risk of bias, we judged three to be at high risk of bias and the remainder were unclear.

Other potential sources of bias

A minority of studies were sufficiently well-reported and conducted for us to be confident that they were at low risk of other sources of bias. While we judged only two studies to be at high risk of bias due to unit of analysis issues (Huang 2007; Thomas 1995), over half the studies were too poorly reported for us to be clear that there were no other potential sources of bias. None of the ten studies which used intra-individual designs for both randomisation and analysis made it clear whether they had used appropriate analytical methods for the paired data. We judged these studies to be unclear for this domain in the 'Risk of bias' assessment (Homann 2007; Khorasani 2009; Liao 2006; Malik 2010; Nasiri 2016; Piatkowski 2011; Radu 2011; Varas 2005; Yang 2013; Zhou 2011). The effect of failure to account for pairing would be to produce wider confidence intervals than the appropriate analysis. Zhou 2011 may be at particularly high risk of carry-over effects from one intervention to another as it randomised burn areas rather than discrete burns.

Effects of interventions

Individual study outcome data are shown in Table 2 (wound healing); Table 3 (wound infection); and Table 4 (secondary outcomes).

Comparison between antiseptics and topical antibiotics

1. Silver-based antiseptic treatments versus topical antibiotics (16 studies, 1368 participants)

Silver-based treatments included silver foam dressings, silver hydrogel dressings, silver alginate dressing, nanocrystalline silver dressing, silver hydrofibre dressing and silver nitrate. In each case the topical antibiotic used was silver sulfadiazine (SSD). Four studies randomised a total of 373 participants and assessed nanocrystalline silver (Chen 2006; Huang 2007; Muangman 2006; Varas 2005). Four studies with a total of 318 participants assessed silver foam dressings (Silverstein 2011; Tang 2015; Yarboro 2013; Zhou 2011). Silver hydrogel dressings were assessed in three studies (Adhya 2015; Glat 2009; Gong 2009; 191 participants) as were silver hydrofibre dressings (Abedini 2013; Caruso 2006; Muangman 2010; 201 participants). Single studies assessed a silver alginate dressing (Opasanon 2010, 65 participants) and silver nitrate treatment (Liao 2006, 120 participants).

Two studies included only children (Glat 2009; Zhou 2011) and three included only adults (Gong 2009, Huang 2007; Varas 2005). The remaining studies included both adults and children or did not report this. Most studies included recent burns described as second-degree or partial-thickness but one (Huang 2007) included only residual burns, unhealed despite previous treatment. The percentage of total body surface area affected (TBSA) was below 40% in all except one study (Adhya 2015 included burns up to 60% TBSA) and several studies imposed lower limits of 10%, 15% or 25%.

Four studies used burns rather than participants as the unit of analysis (Huang 2007; Liao 2006; Varas 2005; Zhou 2011). In Huang 2007 the randomisation was at the level of the participant but the analysis was conducted at the level of the burn wound, that is multiple burns on the same participants were treated with the same treatment and outcome data for the different wounds analysed (clustered data); the other studies employed an intra-individual (split-body) design for both randomisation and analysis; in each case it was not clear whether the analysis had adjusted appropriately. Although Tang 2015 enrolled participants with multiple burns, a single burn was selected at study enrolment and both randomisation and analysis were at the participant level.

Primary outcome: wound healing

Summary of findings table 1
Most studies reported some data on wound healing with this being presented in different ways. There were three studies (259 participants) with sufficient data to calculate a HR for healing and we pooled these data (Caruso 2006; Glat 2008; Tang 2015). In this analysis, on average, the use of silver-containing antiseptics treatment (mainly dressings) showed no clear difference in time to healing compared with SSD; the estimate is imprecise, with CIs spanning benefits and harms (HR 1.25; 95% CI 0.94 to 1.67; I² = 0%) \textbf{Analysis 1.1} (low certainty evidence, downgraded twice for imprecision; confidence intervals included both the possibility of a 6% decrease and a 67% increase in the ‘chance’ of healing).

Mean time to wound healing was reported in ten studies where it seemed that all wounds had healed. On average, silver-containing antiseptic treatments (mainly dressings) may decrease slightly the mean time to healing of burns compared with SSD (MD -3.33 days; 95% CI -4.96 to -1.70; I² = 87%) (low certainty evidence downgraded once for risks of bias (variously detection, selection, reporting and other sources of bias across four of the studies and 30% of the analysis weight) and once for heterogeneity). Although statistical heterogeneity was high, all studies had the same direction of effect and favoured silver-containing antiseptics \textbf{Analysis 1.2}. This was based on nine studies; Silverstein 2011 did not report measures of variance. We used a post-hoc sensitivity analysis to explore the impact of including studies which may not have adjusted for clustered or intra-individual designs. Excluding Huang 2007; Liao 2006; and Zhou 2011 from the analysis resulted in a lower level of heterogeneity (I² = 36%) and a slightly larger estimate of effect (MD -4.53 days, 95% CI -5.74 to -3.32); excluding only trials with intra-individual designs (Liao 2006; and Zhou 2011) or only the trial with unit of analysis issues (Huang 2007) also produced little difference.

The RR for short-term follow-up (maximum 28 days) suggested that on average the use of silver-containing antiseptics may lead to a small difference in number of healing events over one month compared with SSD: RR 1.17 (95% CI 1.00 to 1.37; I² = 45%) \textbf{Analysis 1.3} (low certainty evidence, downgraded once due to risk of detection bias in two studies and selection bias in one study; and once due to imprecision).

\textbf{Primary outcome: infection}

\textbf{Summary of findings table 1}

Incident infections were reported in three studies: Caruso 2006; Glat 2009; Muangman 2006, Tang 2015 reported new signs of wound inflammation which we grouped with the incident infections. It is uncertain whether use of silver-containing antiseptics prevents infection compared with SSD because the certainty of the evidence is very low: RR 0.84 (95% 0.48 to 1.49; I² = 0%) \textbf{Analysis 1.4} (very low certainty evidence, downgraded once each for risk of bias (variously reporting, detection and selection), imprecision and indirectness). Huang 2007 reported bacterial clearance rates (including for specific strains including MRSA); these data are noted in \textbf{Table 3}.

\textbf{Secondary outcome: adverse events}

\textbf{Summary of findings table 1}

Eight studies reported some data on adverse events (Caruso 2006; Glat 2009; Gong 2009; Huang 2007; Silverstein 2011; Tang 2015; Varas 2005; Zhou 2011); six studies reported the proportion of all participants with adverse events. There was no clear difference in the incidence of adverse events between silver-containing antiseptics and SSD in the number of participants with adverse events; the estimate is imprecise with wide CIs spanning benefits and harms: RR 0.86 (95% CI 0.63 to 1.18; I² = 0%) \textbf{Analysis 1.5} (low certainty evidence, downgraded once for risks of bias (variously detection, selection, reporting and other sources of bias) across five of the trials, and once for imprecision). The analyses included six trials, three of which reported that there were no events. We considered a post-hoc sensitivity analysis to explore the impact of including studies that may not have adjusted for clustered or intra-individual designs, however, both Huang 2007 and Zhou 2011 reported zero events and therefore did not contribute weight to the analysis.

Other trials reported data relating to withdrawals or specific event types (Gong 2009) including serious adverse events and withdrawals due to adverse events; these data are not included in the main analysis but are reported separately \textbf{Analysis 1.6; Table 4}. Because one of the two trials (Silverstein 2011; Varas 2005) reporting withdrawals due to adverse events had an intra-individual design we both present pooled data for this analysis and report the results of the trials separately \textbf{Table 4}.

\textbf{Secondary outcome: pain}

Eleven trials reported some data on pain. The most commonly reported measures were pain in general (or at an unspecified time) and pain at dressing change. Caruso 2006; Glat 2009; Muangman 2010; Tang 2015; and Yarboro 2013 reported usable data on pain at dressing change. Gong 2009 reported only the presence of pain at dressing change in the SSD group and its absence in the silver-based antiseptic group, and Silverstein 2011 only that there was no significant difference between the groups.

Silver-based antiseptic treatments may on average slightly reduce pain at dressing change compared with SSD, SMD -1.20 (95% CI -1.92 to -0.49; I² = 81%) (low certainty evidence, downgraded once for imprecision and once for inconsistency). There was significant statistical heterogeneity between the studies, but all of the trials reported lower pain levels in the silver antiseptic group than in the SSD group \textbf{Analysis 1.7}.

A general measure of pain was reported by three trials (Muangman 2006; Opasanon 2010; Varas 2005). Silver-based antiseptic treatments may, on average, slightly reduce generally reported pain compared with SSD. Pain scores may on average be slightly lower in participants treated with silver dressings; the SMD was -1.66 (95% CI -2.06 to -1.27; I² = 0%) \textbf{Analysis 1.8} (low certainty evidence, downgraded once for risk of reporting bias or attrition bias affecting over half the participants and once for imprecision). We used a post-hoc sensitivity analysis to explore the impact of including studies that
may not have adjusted for clustered or intra-individual designs. Excluding Varas 2005 resulted in no change to the estimate of effect but slightly wider confidence intervals (SMD -1.66, 95% CI -2.74 to -0.64; \(i^2 = 0\%\)). Further pain-related measures, which could not be analysed here, are reported in Table 4.

Secondary outcome: mortality

Three trials reported mortality: Caruso 2006; Silverstein 2011 and Muangman 2006. It is uncertain whether silver-containing antiseptic treatments have an effect on mortality. The RR was 1.59 (95% CI 0.20 to 12.64; \(i^2 = 0\%\)) Analysis 1.9. (very low certainty evidence, downgraded once for risks of detection bias and reporting bias and twice for imprecision; two trials at risk of detection bias, one at risk of reporting bias).

Secondary outcome: resource use

Number of dressing changes was reported by six trials (Caruso 2006; Glat 2009; Opasanon 2010; Silverstein 2011; Tang 2015; Yarboro 2013). Participants treated with silver-based antiseptics (dressings) may require fewer dressing changes compared with those treated with SSD. Data from four studies (Silverstein 2011 and Tang 2015 did not report measures of variance) suggests that, on average, silver-containing antiseptics (dressings) may reduce the number of dressing changes, MD -7.56 dressing changes (95% CI -12.09 to -3.04; \(i^2 = 84\%\)) Analysis 1.10 (low certainty evidence, downgraded once for risks of detection and selection bias affecting three trials with 45% of analysis weight, and once for imprecision). The number of minutes of nursing time required was also reported by Opasanon 2010, this also showed that there may be a small benefit to silver-based antiseptics (difference in means -4.82 minutes, 95% CI -7.42 to -2.22) (low certainty evidence, downgraded twice for imprecision) (Table 4). Silverstein 2011 reported mean time to discharge but without measures of variance; the data are shown in Table 4 but are not further analysed.

Secondary outcome: costs

Four trials reported data for total costs of treatment (Abedini 2013; Caruso 2006; Muangman 2010; Silverstein 2011 (based on a subset of 20 participants' data)). It is uncertain whether or not silver-based antiseptic dressings are cheaper overall than SSD. The pooled difference in means across the four trials was USD -117.18 (95% CI -280.02 to 45.67; \(i^2 = 68\%\)) Analysis 1.11. This is very low certainty evidence downgraded once for risk of detection bias in three of the four studies (accounting for over 50% of participants) and twice for imprecision (confidence intervals included both possibilities of cost reduction (USD 280) and increase (USD 46)). Cost-effectiveness data from Caruso 2006 and Silverstein 2011 also showed uncertainty as to whether silver dressings were more cost-effective than SSD (very low certainty evidence, downgraded twice for imprecision and once for risk of detection bias in both studies) (Table 4).

Summary of comparison

Low certainty evidence reporting the hazard or ‘chance’ of healing over time suggested that there may be a small benefit for burns treated with silver-based antiseptics (mainly silver-containing dressings) compared with SSD but confidence intervals were wide, spanning both benefits and harms so clear differences between treatments are not apparent. Low certainty evidence also showed that mean time to healing may be somewhat (3 days) shorter with silver-based antiseptics compared to SSD. There is very low certainty evidence on infection incidence and mortality, meaning that it is unclear what the effect of the different interventions may be. There is low certainty evidence on adverse events suggesting that there may be little or no difference between the treatments. Pain scores may be slightly lower in participants treated with silver compared with SSD (low certainty evidence). Summary of findings table 1

2. Honey or honey-based dressings versus topical antibiotic (11 studies, 856 participants)

Nine studies used honey (variously described as pure, undiluted, unprocessed) (Baghel 2009; Malik 2010; Mashhood 2006; Memon 2005; Maghsoudi 2011; Sami 2011; Subrahmanyam 1991; Subrahmanyam 1998; Subrahmanyam 2001), one a honey dressing (Bangroo 2005) and one oelea which contains honey and olive and sesame oils (Zahmatkesh 2015). Eight studies used SSD as the comparator and two used mafenide acetate (Maghsoudi 2011; Zahmatkesh 2015).

Nine studies included a mix of adults and children (Malik 2010; Mashhood 2006; Memon 2005; Maghsoudi 2011; Sami 2011; Subrahmanyam 1991; Subrahmanyam 1998; Subrahmanyam 2001; Zahmatkesh 2015), one included only adults (Baghel 2009), and one only children (Bangroo 2005). Six studies included participants with burns less than 40% TBSA (Malik 2010; Memon 2005; Maghsoudi 2011; Subrahmanyam 1991; Subrahmanyam 1998; Subrahmanyam 2001); two studies specified less than 50% TBSA (Baghel 2009; Bangroo 2005) and one less than 15% TBSA (Mashhood 2006). One study (Malik 2010) used an intra-individual design and randomised burns on each participant to the treatments.

Primary outcome: wound healing

Summary of findings table 2

All studies reported some measure of wound healing. One study reported the mean time to healing of all wounds but with no measure of variance reported (Baghel 2009). A second study reported full data on only one intervention group (Bangroo 2005). Zahmatkesh 2015 reported the median time to formation of granulation tissue. These data are all presented in Table 2 but are not analysed further.

We could calculate HRs for healing for five studies (Maghsoudi 2011; Malik 2010; Mashhood 2006; Memon 2005; Sami 2011). Honey probably on average reduces time to healing compared with topical antibiotics: HR 2.45 (95% CI 1.71 to 3.52; \(i^2 = 66\%\)) Analysis 2.1 (moderate certainty evidence, downgraded once due to imprecision). This would correspond to an additional 278 (95% CI 185 to 332) more burns healed over time for every 1000 burns treated. We used a post-hoc sensitivity analysis to explore the impact of including the study with an intra-individual design (Malik 2010). The results of this sensitivity analysis differed little from the main analysis (HR 2.31, 95% CI 1.43 to 3.71; \(i^2 = 87\%\)).
Six studies reported the mean time to healing where all wounds healed but for two studies (Baghel 2009; Memon 2005) no measure of variance was available. Honey may slightly shorten the mean number of days to wound healing compared with topical antibiotics. Based on analysis of four studies, the average mean time to healing was -3.79 days (95% CI -7.15 to -0.43; I^2 = 96%) shorter in participants treated with honey compared with those treated with SSD, and all studies showed the same direction of effect despite high statistical heterogeneity Analysis 2.3. We used a post-hoc sensitivity analysis to explore the impact of including the study with an intra-individual design (Malik 2010). The estimate of effect was increased slightly, but wider confidence intervals included the possibility of a small increase in mean time to healing as well as a decrease (MD -4.36 days, 95% CI -8.90 to 0.17; I^2 = 95%). This would be very low certainty evidence, downgraded twice for imprecision and once for inconsistency; in order to be conservative we have adopted the GRADE assessment based on the sensitivity analysis because it ascribes less certainty to the findings than that based on the main analysis.

The RR for short-term follow up (maximum 21 days) also suggested that, on average honey, probably leads to more short-term healing events than topical antibiotic treatment: RR 2.18 (95% CI 1.15 to 4.13; I^2 = 94%). Over a longer period of up to 60 days the RR was 1.65 (95% CI 0.99 to 2.76; I^2 =99%), including the data from the last time points of Mashhood 2006 and Sami 2011. Data from a study which used different time points for the two groups were not included but contribute to the HR (Memon 2005). In each case this is low certainty evidence, downgraded once for imprecision and once for inconsistency.

**Primary outcome: infection**

**Summary of findings table 2**

**Change in infection status**

Eight studies comparing honey with topical antibiotics reported some measure of change in infection status. Four reported incident infection (Malik 2010; Maghsoudi 2011; Subrahmanyam 1998; Zhamatkesh 2015); three reported persistent infection (Sami 2011; Subrahmanyam 1991; Subrahmanyam 2001) and one reported time to healing. In groups treated with honey compared with those treated with SSD, the RR was 0.10 (95% CI 0.05, 0.19; I^2 = 0%) Analysis 2.4. This is very low certainty evidence, downgraded for twice for indirectness in all studies except Maghsoudi 2011 and once for imprecision due to low numbers of events. It was unclear if the analysis in Malik 2010 was adjusted for paired data. Excluding this study in a post-hoc sensitivity analysis did not materially change the result; the RR was 0.09 (95% 0.02 to 0.35; I^2 = 0%).

**Persistent infections**

It is uncertain if fewer burns treated with honey may become infected compared with those treated with topical antibiotics (SSD or mafenide acetate) when assessed at time points between seven and 24 days. The RR was 0.16 (95% CI 0.08 to 0.34; I^2 = 0%) Analysis 2.5. This is very low certainty evidence, downgraded once for imprecision and twice for indirectness in all studies except Maghsoudi 2011. Sami 2011 reported the proportion of participants with continuing positive cultures at multiple time points up to six weeks, at which point all were culture negative (Table 3).

**Secondary outcome: adverse events**

**Summary of findings table 2**

Three studies comparing honey with topical antibiotics reported adverse events for all participants (Maghsoudi 2011; Mashhood 2006; Subrahmanyam 2001). Other trials reported only individual types of events but it was very unclear whether these data related to the number of participants experiencing adverse events or whether multiple events may have been reported for some individuals. These data are noted in Table 4 but are not analysed further. It is uncertain whether fewer participants treated with honey experience adverse events compared with those treated with SSD. There were no events in two trials and two events in the topical antibiotics group in the other trial; the RR was 0.20 (95% CI 0.01 to 3.97; I^2 not calculable) Analysis 2.6. This is very low certainty evidence, downgraded once because of risks of detection bias in Mashhood 2006 and twice because of imprecision.

**Secondary outcome: pain**

Four studies (Bangroo 2005; Mashhood 2006; Subrahmanyam 2001; Sami 2011) reported some data on pain. No study reported pain using a recognised scale and these data are presented in Table 4 but are not further analysed; no GRADE assessment was possible.

**Secondary outcome: resource use**

One study (Subrahmanyam 2001) reported on the length of hospital stay in participants treated with honey or SSD. There is probably a shorter length of stay in participants treated with honey compared with SSD (difference in means -10.30 days, 95% CI -10.95 to -9.65) (Table 4). This is moderate certainty evidence, downgraded once for imprecision. A second study (Sami 2011) reported the amounts of honey or SSD required per dressing per percentage area burned. No measures of variance were reported; these data are reported in Table 4 but are not further analysed; no GRADE assessment was possible.
Secondary outcome: costs

Two studies (Mashhood 2006; Sami 2011) reported on costs of treating burns with honey or SSD but did not report any measure of variance; these data are reported in Table 4 but are not further analysed; without an estimate of effect it is difficult to provide a GRADE assessment for the outcome.

Summary of comparison

Honey on average probably reduces the time to healing compared with topical antibiotics, assessed by evidence reporting the hazard or ‘chance’ of healing over time (moderate certainty evidence). The mean time to healing may, on average, be reduced in wounds treated with honey compared with topical antibiotics (low certainty evidence). Compared with topical antibiotics, honey may, on average, increase the number of healing events assessed over the short term (up to 3 weeks) but it is unclear whether this is still the case when studies with longer follow-up are included (low certainty evidence). It is unclear if there are fewer infections in wounds treated with honey compared with topical antibiotics, and whether fewer initial infections persist (very low certainty evidence). It is uncertain whether the incidence of adverse events differs between groups (very low certainty evidence). Summary of findings table 2

3. Aloe Vera versus topical antibiotics (5 studies, 338 participants)

Four studies compared Aloe Vera to SSD (Khorasani 2009; Panahi 2012; Shahzad 2013; Thamlikitkul 1991) and one compared it to framycetin cream (Akhtar 1996). The Aloe Vera was administered in a variety of creams, gel or dressings. The concentration of Aloe Vera was 0.5% in the one study that reported this (Khorasani 2009).

Three studies included mostly adults (Khorasani 2009; Panahi 2012; Shahzad 2013), one did not report participant age (Akhtar 1996) and in one the mean ages suggested a mix of adults and children (Thamlikitkul 1991). Inclusion criteria for TBSA of burns ranged from less than 5% (Panahi 2012) to less than 40% (Akhtar 1996). One study (Khorasani 2009) used an intra-individual design.

Primary outcome: wound healing

Summary of findings table 3

Four studies reported data on wound healing. Three reported mean time to healing of all wounds (Akhtar 1996; Khorasani 2009; Shahzad 2013). Akhtar 1996 did not report a measure of variance, so these data are reported in Table 2 but are not further analysed. Based on the pooled data from the remaining two studies it is uncertain whether there is a difference in mean time to healing between treatments: average difference in means was -7.79 days (95% CI -17.96 to 2.38; I² = 94%) Analysis 3.1. This is very low certainty evidence, downgraded once for risk of detection bias in a study accounting for 48% of the weight in the analysis (Shahzad 2013), once for inconsistency and twice for very high levels of imprecision. The confidence intervals included the possibility of healing time being shorter by almost 18 days or being two days longer. Because Khorasani 2009 used an intra-individual design, we also note the separate MD for this study (MD -2.85 days, 95% CI -4.04 to -1.66) and Shahzad 2013 (MD -13.24 days, 95% CI -17.91 to -8.57).

One study reported the proportion of wounds healed at 26 days (Thamlikitkul 1991). It is unclear whether Aloe Vera may alter the number of healing events compared with SSD; confidence intervals were wide spanning both benefits and harms so clear differences between treatments are not apparent (RR 1.41, 95% CI 0.70 to 2.85) (Table 2). This is low certainty evidence, downgraded twice for serious imprecision; confidence intervals included the possibility of both a 30% reduction and a 285% increase in the chance of wound healing. None of the studies reported sufficient information for us to calculate an HR for wound healing.

Primary outcome: infection

Summary of findings table 3

Three studies reported data on the incidence of infections at different time points (Khorasani 2009 (24 days); Panahi 2012 (14 days); Shahzad 2013 (unclear time point)).

It is uncertain whether there is a difference between the groups (RR 0.93, 95% CI 0.26 to 3.34; I² = 0%) Analysis 3.2. This is very low certainty evidence, downgraded once for risk of detection bias because 84% of the analysis weight was represented by Shahzad 2013, which had a high risk of detection bias, and twice for imprecision. Very wide confidence intervals included both the possibility of lower (by 74%) or much higher (by over 300%) infection rates in the Aloe Vera groups. Khorasani 2009 which used an intra-individual design reported zero events and therefore a sensitivity analysis to explore the impact of including it in the analysis is not required. Akhtar 1996 reported data on the grade of infection, which is reported in Table 3 but is not further analysed.

Secondary outcome: pain

One study reported the mean reductions in pain scores from baseline (Panahi 2012) and another reported time taken to achieve pain-free status; data from this study were reported differently between the groups and are presented in Table 4 but not analysed further (Shahzad 2013). The data from Panahi 2012 suggest that there is probably a slightly greater decrease in pain in the Aloe Vera group (mean decrease from baseline 5.68) compared with the SSD group (mean decrease from baseline 4.54). The difference in means was 1.14 (95% CI 0.02 to 2.26) (Table 4). This is moderate certainty evidence downgraded once due to imprecision.

Secondary outcome: costs

One study reported data on the cost per percentage of TBSA healed but with no measures of variance (Shahzad 2013). These data are reported in Table 4 but are not further analysed; no GRADE assessment was possible.
Summary of comparison

It is uncertain whether there is a difference in the mean number of days to healing between Aloe Vera and topical antibiotics (very low certainty evidence, downgraded due to detection bias and imprecision). It is unclear whether Aloe Vera may change the proportion of burns healed at 26 days compared with SSD (low certainty evidence, downgraded twice for imprecision). It is uncertain whether there is a difference in the incidence of infection between the groups (very low certainty evidence, downgraded due to detection bias and imprecision). See Summary of findings table 3.

4. Iodine-based treatments versus topical antibiotic (2 studies, 158 participants)

Two studies compared an iodine-based treatment with SSD (Homann 2007; Li 1994). Li 1994 was a four-armed study that compared 0.25% iodophor with SSD, and also included groups treated with ethacridine lactate (Rivanol) and moist burn ointment (see comparisons 8, 12, 16 and 17). There were 115 participants (aged over 16 years) with injuries described as deep second-degree burns between 1% to 12% TBSA in the trial, of whom 62 were in groups relevant to this comparison. Homann 2007 used an intra-individual study design and compared 3% pyrrolidone iodine liposome hydrogel (Repithel) with SSD (10 mg/g) in 43 participants with a mean TBSA of 11%; their age was not reported.

Primary outcome: wound healing

Summary of findings table 4

Both Homann 2007 and Li 1994 reported the mean time to healing of all wounds; this showed that the effect of iodine was very uncertain. The pooled difference in means was -0.47 days (95% CI -2.76 to 1.83; I² = 42%) Analysis 4.1: this is very low certainty evidence, downgraded once due to risk of detection bias for the participants in Homann 2007 and twice due to imprecision; very wide confidence intervals included both the possibility of longer (by 2.8 days) or shorter (by 1.8 days) healing for participants in the iodine antiseptic group. It was not clear whether the analysis accounted for the paired data. Because of the intra-individual design used by Homann 2007 we also report separately the effect estimate for this study (MD -1.40 days, 95% CI -3.39 to 0.59) and for Li 1994 (MD 1.00 days; 95% CI -1.98 to 3.98).

Secondary outcome: adverse events

Summary of findings table 4

Homann 2007 reported data on adverse events in all participants and distinguished local events (which could be related to the different treatments given to the participants). It is uncertain whether there is a difference in incidence of adverse events between the groups; the RR was 0.86 (95% CI 0.35 to 2.10) (Table 4). This is very low certainty evidence, downgraded once due to risk of detection bias and twice due to high levels of imprecision; wide confidence intervals included both the possibility of both a 65% decrease and a 210% increase in events in the intervention group. It is also unclear whether the intra-individual design was accounted for in the analysis.

Secondary outcome: costs

Summary of findings table 4

Li 1994 reported total treatment costs for each intervention group. There may be little or no difference in cost between the iodine and SSD treatments. The mean cost for the iodine group was RMB 621 compared with RMB 674 for the SSD group; the difference in means was RMB -53 (-133.29 to 27.29) Table 4. This is low certainty evidence, downgraded twice due to high levels of imprecision; confidence intervals included both the possibility of substantially lower (RMB -133) and somewhat higher (RMB 27) costs.

Summary of comparison

The effect of iodine-based products on would healing is very uncertain; the confidence intervals for the estimate included the possibility of both benefit and harm (very low certainty evidence, downgraded for risks of bias and imprecision). There were no evaluable data relating to infection. See Summary of findings table 4.

5. Sodium hypochlorite versus topical antibiotics (1 study, 20 participants)

Ning 2008 compared sodium hypochlorite with SSD in 20 adult participants with deep partial-thickness burns less than 60% TBSA. The study used an intra-individual design and randomised comparable burns on the same person to each treatment. It was not clear whether the analysis was adjusted to take account of the paired data.

Primary outcome: wound healing

Ning 2008 reported the mean time to healing for burns treated with each intervention. Sodium hypochlorite may slightly decrease the mean time to healing. Mean time to healing for burns treated with sodium hypochlorite was 20 days compared with 22 days for burns treated with SSD (MD -2.10 days; 95% CI -3.87 to -0.33) Analysis 5.1. This is low certainty evidence because of the very high levels of imprecision (Table 2; Table 5). The confidence intervals were very fragile due to the small number of participants and uncertainty as to whether the paired data were correctly analysed.

Primary outcome: infection

Ning 2008 did not report data on change in infection status.

Secondary outcome: adverse events
Ning 2008 reported that there were no serious adverse events in either treatment group. Total adverse events were not reported. Low certainty evidence, downgraded twice for serious imprecision.

Summary of comparison
Sodium hypochlorite may slightly decrease the mean time to wound healing compared with SSD. This is low certainty evidence, downgraded twice due to imprecision. There were no analysable data for infection.

6. Chlorhexidine or polyhexanide (biguanides) versus topical antibiotics (2 studies, 115 participants)

Piatkowski 2011 randomised 72 burns from 60 adult participants to SSD or a polyhexanide-containing dressing.

Thomas 1995 was a three-armed study that compared chlorhexidine-containing dressing with SSD. A third group were treated with a non-antimicrobial dressing (see comparison 15). Fifty adults and children with a total of 54 burns were randomised; 34 of these burns were treated in groups relevant to this comparison; all burns were described as minor and the mean TBSA was less than 1% in all groups. In both studies it was unclear whether the analyses correctly adjusted for the design of the study with multiple burns from some participants.

Primary outcome: wound healing
Piatkowski 2011 and Thomas 1995 both reported the mean time to wound healing for each group but with no measure of variance. These data are reported in Table 2 but are not further analysed; no GRADE assessment was possible.

Primary outcome: infection
Neither study reported data on infection but Thomas 1995 reported the proportion of wounds with bacteria and pathogenic bacteria at baseline and post treatment; this is noted in Table 3 but the data are not extracted or analysed; no GRADE assessment was possible.

Secondary outcome: pain
Piatkowski 2011 reported pain at dressing change and between dressing changes at a number of time points from baseline up to 14 days. None of these data had any measure of variance so are reported in Table 4 but are not further analysed; no GRADE assessment was possible.

Secondary outcome: costs
Piatkowski 2011 reported costs per day for materials and personnel, and total costs, but without measures of variance. Again these data are shown in Table 4 but are not further analysed; no GRADE assessment was possible.

Summary of comparison
There were no analysable data for either of the primary outcomes or any secondary outcome.

7. Octenidine versus topical antibiotics (1 study, 30 participants)

Radu 2011 used an intra-individual design with 30 adult participants with injuries described as second-degree, partial-thickness burns more than 3% TBSA to compare octenidine with SSD. It was unclear whether the analyses reported took the intra-individual design into account.

Primary outcome: wound healing
Radu 2011 did not report wound healing.

Primary outcome: infection
Radu 2011 did not report change in infection status.

Secondary outcome: pain
Radu 2011 reported that the median VAS for the octenidine group was 3 (range 1 to 6) compared with 6 in the SSD group (range 3 to 8). Mean scores were not reported and these data were not analysed further (Table 4); no GRADE assessment was possible.

Summary of comparison
There were no analysable data for either of the primary outcomes or any secondary outcome.

8. Ethacridine lactate (Rivanol) versus topical antibiotics (1 study, 115 participants)

Li 1994 was a four-armed study that compared ethacridine lactate (Rivanol) with SSD, and also included groups treated with iodophor and moist burn ointment (see comparisons 4, 12, 16 and 17). There were 115 participants (aged over 16 years) with injuries described as deep second-degree burns between 1% to 12% TBSA in the trial, of whom 60 were in groups relevant to this comparison.

Primary outcome: wound healing
Li 1994 reported the mean time to healing of all wounds. There may be little or no difference between participants treated with ethacridine and those treated with SSD in mean time to healing. The difference in means was 2 days (95% CI -0.57 to 4.57) Analysis 6.1. This is low certainty evidence, downgraded twice due to high levels of imprecision; wide and fragile confidence intervals included both the possibility of healing being shorter by half a day or longer by over 4 days (Table 2; Table 5).

Primary outcome: infection
Li 1994 did not report data on change in infection status.

Secondary outcome: costs
Li 1994 reported total treatment costs for each intervention group. There may be little or no difference in costs between the ethacridine lactate and SSD groups. The mean cost per participant was RMB 598 for ethacridine lactate versus RMB 674 for SSD. The difference in means was RMB -76 (95% CI -156.34 to 4.34) (Table 4). This is low certainty evidence, downgraded twice due to serious imprecision; wide and fragile confidence intervals included both a very considerable saving (RMB 156) and a small cost (RMB 4) for the antiseptic intervention.

Summary of comparison
There may be little or no difference in time to healing between the ethacridine lactate and the SSD groups. This is low certainty evidence, downgraded twice due to imprecision. There were no data reported on infections.

9. Merbromin versus topical antibiotic (1 study, 125 participants)
Piccolo-Daher 1990 was a five-armed trial with 125 participants of whom 50 were relevant to this comparison between merbromin and zinc sulphadiazine. Three arms with 75 participants in total were relevant to the review (see comparison 19). Although the unit of analysis was reported to be the burn rather than the participant, it appeared that participants only presented with one burn, therefore we do not believe that there is a unit of analysis issue.

Primary outcome: wound healing
Piccolo-Daher 1990 reported the mean time to wound healing. Merbromin may slightly decrease the mean time to healing compared with zinc sulphadiazine. Mean time to healing was 11.32 days in the merbromin group compared with 14.8 days in the zinc sulfadiazine group. The difference in means was -3.48 (95% CI -6.85 to -0.11). This is low certainty evidence with wide, fragile confidence intervals, downgraded twice due to high levels of imprecision (Table 2; Table 5).

Primary outcome: infection
Piccolo-Daher 1990 did not report data on change in infection status.

Secondary outcomes
Piccolo-Daher 1990 did not report any secondary outcomes.

Summary of comparison
Merbromin may slightly decrease the mean time to healing compared with zinc sulphadiazine (low certainty evidence); there were no data reported on infections.

10. Arnebia euchroma versus topical antibiotic (1 study, 49 participants)
Nasiri 2016 was an intra-individual design trial that randomised burns on 49 participants to the herbal extract of A euchroma or SSD.

Primary outcome: wound healing
Nasiri 2016 reported mean time to healing and the number of healing events at multiple time points, so we were able to calculate an HR. It is unclear whether there is a difference in the ‘chance’ of healing over time between treatment with A euchroma or SSD; this is uncertain as fragile confidence intervals spanned both benefit and harm. The HR was 1.42 (95% CI 0.91 to 2.21). There may be a small difference (3.6 days) in the mean time to healing (95% CI -6.41 to -1.06). In both cases this is low certainty evidence, downgraded twice for imprecision. In both analyses it was unclear whether correct adjustment for the intra-individual design was undertaken; this increases uncertainty around the estimates of effect.

Primary outcome: infection
Nasiri 2016 reported the numbers of burns with an infection score between 0 and 5 for each treatment; one point was awarded for each symptom of infection. These data are reported in Table 3 but are not further analysed; no GRADE assessment was possible.

Secondary outcome: adverse events
Nasiri 2016 reported scores for specific complications such as burning, pain, itching, warming, and incidence of allergic reactions and requiring skin grafts. It was not clear that these represented data on the number of burns with associated adverse events in each group. The data are reported in Table 4 but are not further analysed; no GRADE assessment was possible.

Secondary outcome: pain
Nasiri 2016 reported pain scores graphically at multiple time points after injury (days) and at multiple time points after dressing (minutes). We could not extract confidence intervals from the graphs but all were reported by study authors to have differences between groups (P reported < 0.05). The data are noted in Table 4 but are not further analysed; no GRADE assessment was possible.

Summary of comparison:
It is unclear whether there is a difference in time to healing between treatment with A euchroma or SSD assessed by the hazard or ‘chance’ of healing over time. There may be a small reduction in the mean time to healing in burns treated with A euchroma compared with those treated with SSD. In both cases this is low certainty evidence. There were no evaluable
data on the incidence of infection.

**Comparisons between two antiseptics**

11. Chlorhexidine versus povidone iodine (1 study, 213 participants)

Han 1989 enrolled 213 participants with burns less than 10% TBSA; approximately 20% were children. Participants were randomised to Bactigras (tulle-gras wide-meshed gauze dressing impregnated with 0.5 per cent chlorhexidine acetate BP) or Inadine (synthetic rayon dressing impregnated with 10 per cent povidone iodine ointment).

**Primary outcome: wound healing**

Han 1989 reported mean time to wound healing. There may be a slightly increased mean time to healing in the chlorhexidine group. Mean time to healing was 11.69 days in the chlorhexidine group compared with 9.48 in the iodine group. The difference in means was 2.21 days (95% CI 0.34 to 4.08) (Analysis 8.1). This is low certainty evidence, downgraded once due to risk of reporting bias and once due to imprecision because of wide confidence intervals (Table 2; Table 5).

**Primary outcome: infection**

Han 1989 reported incident infections in each group. It is uncertain whether there is a difference in infection incidence between the treatments. There were 4/102 in the chlorhexidine and 4/111 in the povidone iodine groups. The RR was 1.09 (95% CI 0.28 to 4.24). This is very low certainty evidence, downgraded once due to risk of reporting bias and twice due to very serious imprecision (Table 3; Table 5).

**Secondary outcome: resource use**

Han 1989 reported the mean number of hospital visits for each participant in the two treatment groups. There may be little or no difference between the chlorhexidine and povidone iodine groups on either measure of pain. The mean VAS score for pain at rest was 11.44 in the chlorhexidine group and 9.18 in the povidone iodine group. The difference in means was 2.26 (95% CI -2.26 to 6.78). The mean score for pain at dressing change was 8.75 in the chlorhexidine group and 6.66 in the povidone iodine group. The difference in means was 2.09 (95% CI -2.00 to 6.18) (Table 4). In both cases this is very low certainty evidence, downgraded once due to risk of reporting bias and twice for very serious imprecision; wide confidence intervals included the possibility of both lower (-2) and much greater pain scores (+6) in the chlorhexidine group.

**Summary of comparison**

Chlorhexidine-based dressings may result in a slightly longer mean time to healing than povidone iodine dressings (low certainty evidence, downgraded due to risk of bias and imprecision). It is uncertain whether there is a difference between chlorhexidine and povidone iodine in the number of incident infections in burn wounds (very low certainty evidence, downgraded due to risk of bias and serious imprecision).

12. Iodophor versus ethacridine lactate (1 study, 115 participants)

Li 1994 was a four-armed study that compared 0.25% iodophor with ethacridine lactate, and also included groups treated with SSD and moist burn ointment (see comparisons 4, 8, 16 and 17). There were 115 participants (aged over 16 years) with injuries described as deep second-degree burns between 1% to 12% TBSA in the trial, of whom 53 were in groups relevant to this comparison.

**Primary outcome: wound healing**

Li 1994 reported mean time to wound healing. There may be little or no difference in healing time between participants treated with iodophor and those treated with ethacridine lactate. Mean time to healing was 31 days in the iodophor group compared with 32 days in the ethacridine lactate group (MD -1.00 day (95% CI -4.31 to 2.31) (Table 2; Table 5). This is low certainty evidence due to high levels of imprecision; wide confidence intervals included the possibility of both a shorter healing time by 4 days and a longer healing time by 2 days for the iodine group.

**Primary outcome: infection**

Li 1994 did not report data on change in infection status.

**Secondary outcome: costs**

Li 1994 reported total treatment costs for each intervention group. There may be little or no difference in costs between the iodine and ethacridine-lactate groups. The cost per participant was RMB 621 in the iodine group compared with RMB 598 in the ethacridine-lactate group. The difference in means was RMB 23.00 (95% CI -51.07 to 97.07) (Table 4). This is low certainty evidence, downgraded twice due to high levels of imprecision resulting from small numbers of participants; wide confidence intervals included both the possibilities of a saving of RMB 51 and an additional cost of RMB 97.

**Summary of comparison**

There may be little or no difference in mean time to healing for participants treated with iodophor or ethacridine lactate (low certainty evidence). There were no data on infection.
13. Silver dressings versus non-antimicrobial treatments or no treatment (3 studies, 299 participants)

**Chen 2006** was a three-armed trial that randomised 191 participants with burns described as being second-degree to a silver nanoparticle dressing or to Vaseline gauze. A third group of participants were treated with SSD (see comparison 1). The number of participants in groups relevant to this comparison was 128. **Jiao 2015** randomised 76 participants with partial-thickness burns to nanocrystalline silver or Vaseline gauze; in each case the dressing was applied over human epidermal growth factor. **Healy 1989** randomised 32 participants (mostly children) to silver-impregnated porcine xenograft or paraffin gauze.

**Primary outcome: wound healing**

**Summary of findings table 5**

**Healy 1989** reported the proportion of wounds completely healed in each group by 14 days. There may be little or no difference between silver xenograft and paraffin gauze in proportion of wounds healed; 9/16 wounds healed in the silver group compared with 8/16 in the control group. The RR was 1.13 (95% CI 0.59 to 2.16) (low certainty evidence, downgraded twice because of serious imprecision) **Table 2**. The mean time to healing of these wounds was also reported but as not all wounds healed these data are reported in **Table 2** but are not further analysed.

**Chen 2006** and **Jiao 2015** reported the mean time to healing for all wounds. The mean time to healing is probably slightly shorter in the silver group compared with the gauze group; -3.49 days (95% CI -4.46 to -2.52; I² = 0%) a reduction from 15.87 days in the gauze group to 12.38 days. This is moderate certainty evidence downgraded because of imprecision.

**Primary outcome: infection**

**Summary of findings table 5**

It is very uncertain whether there is a difference in wound infections between silver and non-antimicrobial treatments. **Jiao 2015** reported the proportion of wounds testing positive for bacteria at 21 days as 1/38 in the silver group and 8/38 in the gauze group. The RR was 0.13 (95% CI 0.02 to 0.95). However this is not a measure of clinical infection. **Healy 1989** reported data on specific bacteria colonisation but otherwise reported only that there was no difference in the infection rate between the groups; these data are noted in **Table 3**. This is very low certainty evidence, downgraded once for indirectness and twice for imprecision.

**Secondary outcomes**

Neither **Chen 2006** nor **Healy 1989** reported data on any secondary outcome while **Jiao 2015** reported only one specific type of adverse event (scar hyperplasia); this is noted in **Table 4** but is not further analysed.

**Summary of comparison**

Silver xenograft may make little or no difference to the proportion of burn wounds that heal by 14 days compared to a non-antimicrobial (paraffin gauze) dressing (low certainty evidence downgraded twice for imprecision). Silver nanoparticle dressings probably result in burns healing in a slightly shorter mean time compared with Vaseline/petroleum gauze (moderate certainty evidence downgraded for imprecision). It is very uncertain whether there is any difference between the dressings in infection rates (very low certainty evidence downgraded for indirectness and imprecision) **Summary of findings table 5**.

14. Honey or honey-based dressings versus non-antimicrobial treatments (3 studies, 256 participants)

**Subrahmanyam 1993b** randomised 92 participants to honey-impregnated gauze or a bio-occlusive, moisture-permeable polyurethane dressing. **Subrahmanyam 1994** randomised 64 participants to honey-impregnated gauze or amniotic membrane; no other details of the comparison dressing were given. **Subrahmanyam 1996a** randomised 100 participants to honey plus dry gauze or an autoclaved potato peeling dressing plus dry gauze. All studies enrolled a mixture of adults and children, although most participants were adults where reported. All three studies enrolled participants with partial-thickness burns less than 40% TBSA. **Subrahmanyam 1996b** compared honey with a mixed standard treatment group in which the following treatments were used: soframycin (90 participants), Vaseline-impregnated gauze (90 participants), OpSite (90 participants), sterile gauze (90 participants) or left exposed (90 participants).

**Primary outcome: wound healing**

**Summary of findings table 6**

Two trials reported data at numerous time points allowing hazard ratios for healing to be calculated (**Subrahmanyam 1994, Subrahmanyam 1996a**). Honey probably somewhat increases the 'chance' of healing over time for partial-thickness burns compared with non-anti-microbial treatments. The pooled HR was 2.86 (95% CI 1.60 to 5.11; I² = 50%) **Analysis 6.1**. This is moderate certainty evidence downgraded once for imprecision. All wounds healed in both groups over the total time period assessed, but the hazard ratio corresponds to the increased likelihood of healing at earlier time points in the honey groups. As HRs could be calculated for all trials with dichotomous data, we have not reported RRs.

All four trials also reported mean times to healing, or data were available as a result of contact with the study author by a previous Cochrane Review (**Jull 2015**). On average, honey results in a somewhat shorter mean time to healing compared with the non-antibacterial dressings evaluated. The pooled difference in means was -5.32 days (95% CI -6.30 to -4.34; I² = 71%) **Analysis 6.2**. This is high certainty evidence although some of the comparators used are atypical.
Primary outcome: infection

Summary of findings table 6

Three trials reported a measure of infection. However this was based on swab cultures which are only an indirect measure of infection and do not correspond to clinical infections. Subrahmanyam 1993b reported incidence of infection on day 8 in both groups. It is uncertain whether there may be fewer incidences of infection in wounds treated with honey compared with polyurethane dressing. There were 8/46 infections reported in the honey group compared with 17/46 in the polyurethane dressing group. The RR was 0.47 (95% CI 0.23 to 0.98) (very low certainty evidence, downgraded twice for imprecision and twice for indirectness).

Subrahmanyam 1994 and Subrahmanyam 1996a reported incidence of persistent positive swab cultures at day 7. It is uncertain whether persistent infections differ in participants treated with honey compared with participants treated with comparator topical treatments. The total number of participants considered to have a persistent infection was 8/78 in the honey groups compared with 53/69 in the non-antibacterial groups. The pooled RR for persistent infection at day 7 was 0.15 (95% CI 0.06 to 0.40; I² = 50%) Analysis 6.3. This is very low certainty evidence, downgraded twice for indirectness and once for imprecision.

Secondary outcome: adverse events

Summary of findings table 6

Subrahmanyam 1993b and Subrahmanyam 1994 reported information on some adverse events but it was not clear that these represented all reported adverse events. Subrahmanyam 1996a reported that there were no adverse events in either the honey or the SSD group. This is very low certainty evidence, downgraded twice for serious imprecision and indirectness.

Secondary outcome: pain

Subrahmanyam 1994 measured pain using a four-point scale and reported the number of participants in each group with no or mild pain and with moderate or severe pain. The mean scores were not reported and these data are not further analysed. Subrahmanyam 1996a reported only that subjective relief of pain was the same in both treatment groups. These data are reported in Table 4 but are not further analysed; no GRADE assessment was possible.

Summary of comparison

Based on the hazard or 'chance' of healing over time, honey probably, on average, somewhat shortens the time to healing for partial-thickness burns compared with a range of non-antibacterial alternatives, including treatments not commonly used in clinical practice. There is high certainty evidence of some reduction in the mean time to wound healing in the wounds treated with honey. It is uncertain if burns treated with honey may develop fewer infections than those treated with the comparison treatments. Summary of findings table 6.

15. Chlorhexidine (biguanide) versus non-antimicrobial treatments (5 studies, 516 participants)

Five studies compared chlorhexidine with no treatment or a non-antimicrobial treatment. Inman 1984 randomised 121 participants to SSD plus chlorhexidine versus SSD alone in participants with full-thickness burns; full-thickness injuries were less than 15% TBSA. Other studies used chlorhexidine-impregnated paraffin gauze or tulle-gras. Neal 1981 (51 participants), Phipps 1988 (196 participants) and Thomas 1995 (50 participants) enrolled people with burns less than 5% TBSA while Wright 1993 (98 participants) required that burns be suitable for outpatient treatment. Comparators were plastic film dressing (Neal 1981) or hydrocolloid dressing (Phipps 1988; Thomas 1995; Wright 1993). Where reported, all studies enrolled a mix of adults and children. Thomas 1995 also assigned participants to a third arm treated with SSD (see comparison 6). As previously noted, some participants in Thomas 1995 had multiple burns analysed in the study, creating unit of analysis issues.

Primary outcome: wound healing

Summary of findings table 7

Neal 1981 reported the number of participants whose wounds healed at multiple time points and presented a Kaplan-Meier curve. The trial did not show a clear difference between chlorhexidine and non-antimicrobial film dressing in time to wound healing; wide and fragile CIs spanned both benefit and harm so a clear treatment effect is not apparent. The calculated HR, based on 25 participants in the chlorhexidine group and 26 in the film-dressing group, was 0.71 (95% CI 0.39 to 1.29) (Table 2). Neal 1981 also reported the mean time to healing. This indicated that the mean time to healing may be slightly longer (14 days) in the chlorhexidine group (compared with 10 days in the film dressing group) with a difference in means of 4.08 days (95% CI 0.73 to 7.43); again the estimate was imprecise. Both Phipps 1988 and Thomas 1995 reported the mean time to healing in each group but did not report a measure of variance. Wright 1993 reported the median time to wound healing in each group. The data for these three trials are reported in Table 2 but are not further analysed. All the evidence is low certainty, downgraded twice because of serious imprecision due to low participant numbers, wide confidence intervals and poor reporting. The three trials that did not present analysable data were also all at high risk of bias across one or more domains. Because the study that had unit of analysis issues did not contribute to the analysis, (Thomas 1995) no sensitivity analysis was undertaken.

Primary outcome: infection

Summary of findings table 7

Inman 1984 reported the numbers of participants in each group with infection. It appeared that there were a number of post-randomisation exclusions from the study, numbers are reported on a completed case basis. Neal 1981 reported the
proportion of participants in each group with proven infections. It is uncertain whether there is a difference between the treatments. On average the RR for wound infection from these two studies was RR 1.11 (95% CI 0.54 to 2.27; I² = 0%) (Analysis 7.2). This is very low certainty evidence, downgraded twice due to high levels of imprecision and once due to attrition bias in Inman 1984: wide confidence intervals included the possibility of both substantial benefits and harms associated with the intervention.

Phipps 1988 reported proportions of participants with specific wound flora and Thomas 1995 reported percentages of wounds with bacteria and pathogenic bacteria; these data are noted in Table 3 but are not further analysed.

Secondary outcome: adverse events

Wright 1993 reported the number of participants with an adverse event in each group. It is uncertain whether chlorhexidine decreases the number of people experiencing adverse events. In the chlorhexidine group, 1/49 participants experienced an adverse event, compared with 5/49 in the comparison group. The RR was 0.20 (95% CI 0.02 to 1.65) (Table 4). This is very low certainty evidence, downgraded once due to risk of detection bias, once due to attrition bias and twice due to very high levels of imprecision as a result of very wide confidence intervals, which included a possible 98% reduction and also a 65% increase in events associated with the antiseptic intervention.

Secondary outcome: pain

Inman 1984 reported the numbers of participants in each group with pain sufficient to stop treatment. Neal 1981 reported qualitatively that chlorhexidine treatment was perceived as painful. Wright 1993 reported summing the VAS for each visit; the scores were not reported but a P value was given. All these data are reported in Table 4 but are not further analysed; no GRADE assessment was possible.

Secondary outcome: mortality

Inman 1984 reported total and infection-related mortality in each treatment group. It is uncertain whether chlorhexidine in addition to SSD alters mortality. A total of 3/54 people died in the chlorhexidine group compared with 4/67 in the SSD-alone group. The RR was 0.93 (95% CI 0.22 to 3.98) (Table 4). This is very low certainty evidence, downgraded once for attrition bias and twice for very serious imprecision due to wide confidence intervals, which included a possible 78% reduction and an almost 400% increase in deaths.

Secondary outcome: resource use

Despite being evaluated in multiple trials the evaluable data were limited. There may be little or no difference in the time to wound healing between chlorhexidine and a film dressing (low certainty evidence downgraded twice for imprecision). It is uncertain whether the use of chlorhexidine reduces the incidence of infection compared with no additional antibacterial treatment (very low certainty evidence, downgraded twice due to imprecision and once due to attrition bias). It is also uncertain whether use of chlorhexidine plus SSD reduces mortality compared with SSD alone (very low certainty evidence, downgraded twice for imprecision and once for risk of attrition bias). Summary of findings table 7

16. Iodine-based treatments versus non-antimicrobial treatments/no intervention (4 studies, 663 participants)

Carayanni 2011 randomised 217 participants with superficial or deep partial-thickness thermal burns less than 15% TBSA to povidone iodine with a barrier of bepanthenol cream or MEBO. Randomisation was stratified by burn depth. Li 1994 was a four-armed study that compared iodophor with moist burn ointment and also included groups treated with SSD and ethacridine lactate (see comparisons 4, 8, 12 and 17). There were 115 participants (aged over 16 years) with injuries described as deep second-degree burns between 1% to 12% TBSA in the trial, of whom 55 were in groups relevant to this comparison. Li 2006 randomised 277 participants with superficial, deep or residual burn wounds to iodine gauze or to carbon fibre dressing. Yang 2013 enrolled 60 participants with residual burn wounds after one month of treatment and randomised burn areas to iodophor gauze or to a hydrogel dressing; this was an intra-individual design.

Primary outcome: wound healing

Summary of findings table 8

Yang 2013 reported the proportion of wounds healed at seven and 14 days. Iodophor gauze may reduce the chances of residual burn wounds healing after 14 days: RR was 0.17 (95% CI 0.08 to 0.34) (Table 2). It was unclear whether the analysis adjusted for the paired data from the intra-individual design. This is low certainty evidence, downgraded twice for imprecision due to uncertainties about the analysis and small numbers of participants.

Li 1994 reported mean time to wound healing as did Li 2006. It is unclear whether the use of iodine reduces the mean time to healing because the certainty of the evidence is very low. Clinical differences in the treatments used and very high levels of statistical heterogeneity (I² = 99%) meant that pooling was unlikely to produce a meaningful answer. Li 1994 reported that mean time to healing for wounds was 31 days in the iodophor group and 57 days in the MEBO group (Li 1994), with a difference in means of -26 days (95% CI -30.48 to -21.52). Li 2006 reported that mean time to healing for wounds was 20.67 days in the iodine-gauze group compared with 15.29 days in the carbon-dressing group, with a difference in means of 5.3 days (95% CI 3.09 to 7.67) (Analysis 8.1). This is very low certainty evidence, downgraded twice for inconsistency and twice for imprecision.
Primary outcome: infection

**Summary of findings table 8**

Carayanni 2011 reported the numbers of participants with infection. There may be little or no difference between iodine and MEBO in the incidence of infections. There were 8/107 participants with infections in the iodine group compared with 6/104 in the MEBO group. The RR was 1.30 (95% CI 0.47 to 3.61). This is low certainty evidence, downgraded twice for very high levels of imprecision with wide confidence intervals, which included the possibility of a both a reduction of 53% and an increase of 360% in infection rates for the iodine intervention (Table 3).

Yang 2013 reported bacterial presence in wounds and stated that there was no evidence of a difference between the groups (Table 3); these data were not further analysed.

Secondary outcome: adverse events

**Summary of findings table 8**

Carayanni 2011 reported adverse events including infections. There may be little or no difference between iodine and MEBO in the incidence of adverse events. There were 8/107 participants with reported events (all infections) in the iodine group and 11/104 in the MEBO group. The RR was 0.71 (95% CI 0.30 to 1.69). This is also low certainty evidence, downgraded twice due to the very high levels of imprecision with wide confidence intervals, which included the possibility of a 70% reduction or a 70% increase in events for the iodine intervention (Table 4).

Secondary outcome: costs

**Summary of findings table 8**

Carayanni 2011 reported mean time to wound healing. Mean time to wound healing may be reduced in the ethacridine lactate group compared with the MEBO group. Mean times to heal were 32 days for the ethacridine group and 57 days for the MEBO group; the difference in means was -25 days (95% CI -29.21 to -20.79). This is low certainty evidence, downgraded twice due to high levels of imprecision resulting from small numbers of participants.

17. Ethacridine lactate versus non-antimicrobial treatments (1 study, 115 participants)

Li 1994 reported total treatment costs for each intervention group. Total costs may be lower in the ethacridine lactate group compared with the MEBO group. Costs in the ethacridine group were RMB 598 compared with RMB 1836 for people in the MEBO group. The difference in means was RMB -1238 (95% CI -1435.98 to -1040.22) Table 4. This is low certainty evidence, downgraded twice due to very high levels of imprecision with wide confidence intervals, which included the possibility of a 70% reduction or a 70% increase in costs for the iodine intervention (Table 4).

Secondary outcome: resource use

Carayanni 2011 reported reduction in length of hospital stay in participants treated with iodine compared with those treated with MEBO. There was a reduction of 3.01 days in the iodine group compared with 3.63 in the MEBO group; the difference in means was 0.62 days (95% CI 0.05 to 1.19) (Table 4). This is moderate certainty evidence, downgraded once for imprecision due to low numbers of participants.

Secondary outcome: pain

Yang 2013 reported median pain scores in graphical form only. In both cases these data are noted in Table 4 but are not extracted or analysed further; no GRADE judgement was possible.

Summary of comparison

It is uncertain whether iodine-based treatments decrease or increase the mean time to healing compared with treatments without antibacterial properties (very low certainty evidence downgraded twice due to inconsistency and twice for imprecision). Iodophor gauze may reduce the chances of residual burn wounds healing within 14 days compared with hydrogel treatment (low certainty evidence downgraded twice due to imprecision). There may be little or no difference in the occurrence of either infections or adverse events including infections, between povidone iodine and a non-antibacterial comparator (low certainty evidence downgraded twice due to imprecision) Summary of findings table 8.

**Table 3**

**Table 4**

**Table 5**

**Table 6**

**Table 7**

**Table 8**
evidence downgraded twice due to high levels of imprecision resulting from small numbers of participants.

Summary of comparison
There may be a shorter mean time to healing in burns treated with ethacridine lactate compared with MEBO. This is low certainty evidence due to high levels of imprecision and fragile confidence intervals. There were no data on infection.

18. Cerium nitrate + topical antibiotic versus topical antibiotic alone (2 studies, 214 participants)

Oen 2012 randomised 154 adults with facial burns to cerium nitrate plus SSD or SSD alone while De Gracia 2001 randomised 60 participants with full or partial-thickness burns to the same interventions.

Primary outcome: wound healing

De Gracia 2001 found that the effect of treatment with cerium nitrate in addition to SSD is unclear in terms of the number of participants with sepsis at up to five days and then subsequently compared with SSD alone. In total 1/30 participants in the cerium nitrate group had sepsis versus 4/30 in the control group. The RR was 0.25 (95% CI 0.03 to 2.11) so the wide confidence intervals included the possibility of both benefit and harm. This was also the case for the number of participants with post-treatment infection compared with SSD alone; 3/30 participants developed an infection in the cerium nitrate group compared with 6/30 in the control group (RR 0.50, 95% CI 0.14 to 1.82). In both cases this is low certainty evidence, which was downgraded twice due to serious imprecision because of low numbers of events and participants (Table 3; Table 5).

Oen 2012 did not report data on change in infection status.

Secondary outcome: pain

Oen 2012 reported mean pain scores both generally and for procedures. Cerium nitrate plus SSD probably slightly reduces overall pain scores. In the cerium nitrate group the mean score was 0.6 compared with 1.2 in the control group. The difference in means was -0.60 (95% CI -0.70 to -0.50) Table 4. This is moderate certainty evidence downgraded once for imprecision due to the small number of participants.

Secondary outcome: mortality

Both De Gracia 2001 and Oen 2012 reported the number of participants who died in each treatment group. Cerium nitrate plus SSD may reduce mortality compared with SSD alone. There were 2/108 deaths in the cerium nitrate group compared with 9/106 in the SSD-alone group. The RR was 0.22 (95% CI 0.05 to 0.99; I² = 0%) Analysis 9.1. This is low certainty evidence downgraded twice due to imprecision because of wide confidence intervals, which were fragile due to low numbers of both events and participants. In one of the trials (Oen 2012) deaths occurred during the enrolment process so the effect of treatment group is unclear.

Secondary outcome: resource use

De Gracia 2001 reported the mean length of hospital stay. It is unclear whether cerium nitrate in addition to SSD reduces hospital stay. The mean length of stay was 23.3 days in the cerium nitrate group versus 30.7 days in the control group. The difference in means was -7.4 days (95% CI -16.49 to 1.69) Table 4. This is low certainty evidence downgraded twice due to imprecision because of wide confidence intervals, which included both a substantial benefit (16.5 days) for the cerium nitrate group and a small benefit (1.7 days) for the comparison group.

Summary of comparison

There were no analysable data on wound healing. The effect of cerium nitrate in addition to SSD on rates of infection and of sepsis is unclear, compared with SSD alone (low certainty evidence with wide confidence intervals including both benefit and harm, downgraded twice for imprecision). There may be lower mortality rates in the cerium nitrate group compared with the group treated with SSD alone (low certainty evidence, downgraded twice due to serious imprecision).

19. Merbromin versus sodium salicylate (1 study, 125 participants)

This comparison was addressed by one trial. Piccolo-Daher 1990 was a five-armed trial with 125 participants of whom 50 were relevant to this comparison. Three arms with 75 participants in total were relevant to the review (see comparison 9). As above, although the unit of analysis was reported to be the burn rather than the participant it appeared that participants only presented with one burn, therefore we do not believe that there is a unit of analysis issue.

Primary outcome: wound healing

Piccolo-Daher 1990 found that the mean time to wound healing may be slightly reduced in participants treated with merbromin (11.32 days) compared with those treated with sodium salicylate (15.0 days). The difference in means was -3.68 days (95% CI -7.18 to -0.18). This is low certainty evidence downgraded twice due to imprecision (Table 2; Table 5).

Primary outcome: infection

Piccolo-Daher 1990 did not report data on change in infection status.
Secondary outcomes

Piccolo-Daher 1990 did not report any secondary outcomes.

Summary of comparison

Burns treated with merbromin may have a slightly shorter mean time to healing than those treated with sodium salicylate (low certainty evidence downgraded twice due to serious imprecision). There were no data on infection.

Discussion

Summary of main results

We identified 56 eligible studies with 5807 randomised participants. The majority of these assessed treatments with antiseptic properties and compared them to the topical antibiotic silver sulfadiazine. Most participants appeared to be adults, although the majority of studies enrolled both adults and children. In most studies burns were required to correspond to a classification (by the studies' authors) of second degree and to be under 40% TBSA. Some studies focused on smaller and more superficial burns and a smaller number allowed some deeper burn areas. A minority of participants had residual burn wounds, but the great majority were enrolled in the period immediately after the injury.

Wound healing

Antiseptics compared with topical antibiotics

Evidence on wound healing is mixed and largely of low certainty due to small sample sizes and wide confidence intervals.

Measuring the hazard or 'chance' of healing over time using a HR suggested that there is no clear difference in time to healing between wounds treated with silver-based antiseptics (mainly dressings) and those treated with topical antibiotics (all SSD); this is low certainty evidence as data came from 259 participants, and the 95% CIs spanned effects of both benefit and harm for the intervention. Low certainty evidence from a larger number of studies (979 participants), reporting mean time to healing of all wounds, suggested that there may be a modest benefit of healing time, approximately three days shorter in the silver-based antiseptics arm; while studies that reported dichotomous healing data also suggested that there may be little difference in how many wounds treated with silver antiseptics may heal by three or four weeks compared with those treated with SSD.

Measuring the hazard or 'chance' of healing over time using an HR suggested that wounds treated with honey probably have a somewhat shorter time to healing than wounds treated with topical antibiotics (moderate certainty evidence based on 580 participants). There may, on average, be a greater number of healing events measured at short term (21-day follow-up) (low certainty evidence). It is uncertain whether there is a difference in mean time to healing (very low certainty evidence)

It is unclear whether there is a difference in the number of healing events over a 26-day period in burns treated with Aloe Vera compared with SSD. It is uncertain if the overall average effect of mean time to healing differs between these treatments (very low certainty evidence). There is low certainty evidence that sodium hypochlorite may be associated with a mean time to healing that was lower by around two days than for SSD. Also with low certainty evidence, there may be a small benefit (around 3.5 days) in mean time to healing from merbromin compared with zinc sulfadiazine. There is low certainty evidence that there may be a similar small benefit of around 3.6 days for treatment with extract of the herb A euchroma, which has antiseptic properties, compared with SSD, but it was unclear whether there was a difference in the 'chance' of healing over time. There is low certainty evidence that there may be little or no treatment difference in wound healing for the comparisons of ethacridine lactate or iodine-based treatments with silver sulfadiazine. There were no usable data for the primary outcomes from trials comparing chlorhexidine, polyhexanide or octenidine to silver sulfadiazine.

Antiseptics compared with alternative antiseptics

There were few comparisons between different antiseptics. Low evidence from a single trial indicated that there may be a small benefit of around two days in mean time to healing for wounds treated with povidone iodine compared with chlorhexidine. There may be little or no difference between iodophor and ethacridine lactate in wound healing times (low certainty evidence).

Antiseptics compared with non-antibacterial alternative treatments

Several different antiseptic agents were compared with a range of dressings without antibacterial properties. The evidence from these comparisons is generally of low certainty.

There is moderate certainty evidence, based on 204 participants in two trials that, on average, burns treated with nanocrystalline silver dressings have a slightly shorter mean time to healing (by around 3.5 days) than those treated with Vaseline gauze. There is low certainty evidence that there may be little or no difference in the number of healing events at 14 days between burns treated with silver xenograft or paraffin gauze.

Measuring the hazard or 'chance' of healing over time using a HR suggested that wounds treated with honey probably, on average, have a somewhat shorter time to healing than wounds treated with unconventional non-antibacterial treatments, based on 164 participants treated with honey compared with amniotic membrane or potato peelings (moderate certainty evidence). There is high certainty evidence for a shorter average mean time to healing in burns treated with honey compared with non-antibacterial treatments, including the unconventional ones assessed using the HR. Burns healed, on average, in a mean time which was 5.3 days shorter in groups treated with honey.

Combinations involving iodine-based treatments produced contradictory results favouring both iodine and the comparator in terms of mean time to healing; it is uncertain where the true treatment effect may lie (very low certainty evidence). There may
be fewer healing events over a short follow-up period in wounds treated with iodophor gauze compared with hydrogel (low certainty evidence). Honey was compared with a range of treatments, some of which were unconventional. There is also low certainty evidence that both merbromin and ethacridine lactate may result in shorter mean times to healing compared with a non-antibacterial treatment.

**Infection**

Antiseptics compared with topical antibiotics

Most comparisons did not report data on this key outcome but the comparisons of silver and Aloe Vera with SSD showed that there may be little or no difference between the treatment arms (low certainty evidence). There is uncertainty as to the effect of treatment with honey compared with SSD on infections (very low certainty evidence).

Antiseptics compared with alternative antiseptics

It is uncertain whether there was a difference in infections between chlorhexidine and povidone iodine (very low certainty evidence). There were no data on any other comparisons between antiseptics.

Antiseptics compared with non-antibacterial alternative treatments

It is uncertain whether there were differences in burns treated with either silver-based dressings or honey compared with a range of non-antimicrobial treatments, some of which were unconventional; this is very low certainty evidence in both cases. There is moderate certainty evidence of no difference in infection rates for a comparison of an iodine-based treatment with MEBO. The only comparison that showed any evidence of a benefit in infection reduction was the use of cerium nitrate in addition to silver sulfadiazine, compared with silver sulfadiazine alone, where there is some low certainty evidence of a reduced incidence of infections and sepsis. Other comparisons did not report usable data on infection rates.

**Secondary outcomes**

Adverse events were not reported for many comparisons, or they were reported in qualitative terms, which made it difficult to determine event rates for each intervention group, or they were reported only for specific types of event. There may be little or no difference in adverse events for any of the comparisons that did report the number of participants with an adverse event in each group; or the impact of treatments on adverse effects is very uncertain (low or very low certainty evidence).

Mortality was low where reported and there may be little or no difference between treatment groups in most comparisons; this was based on very small numbers of events and is low certainty evidence. The exception was the comparison of cerium nitrate plus SSD with SSD alone, where there may be fewer deaths in the cerium nitrate groups; again, event rates were low and this is low certainty evidence based on 214 participants in two trials.

Pain is of particular concern to people with burns and medical personnel: often this was not reported in sufficient detail for us to analyse but there was evidence that there may be lower levels of pain in participants treated with silver dressings compared with silver sulfadiazine (low certainty evidence). Pain probably decreases slightly more from baseline in those treated with Aloe Vera compared with SSD (moderate certainty evidence). There is also some low certainty evidence that participants treated with cerium nitrate plus SSD may have less pain than those treated with SSD alone. It was uncertain whether there was a difference in pain between participants treated with chlorhexidine and those treated with povidone iodine (very low certainty evidence).

Resource use was reported for a limited number of comparisons. Frequency of dressing changes and associated implications for nursing time and costs were the most commonly reported outcomes under this heading. There was some evidence that participants treated with silver dressings may require fewer dressing changes than those treated with SSD (low certainty evidence) and some evidence that participants who are treated with honey probably have a shorter hospital stay compared with those treated with SSD (moderate certainty evidence). Reduction from an expected length of stay in hospital is probably smaller in participants treated with iodine-based dressings compared with MEBO (moderate certainty evidence). With a few exceptions, costs were not adequately reported or showed that there may be no differences between treatment groups. In some cases there may be cost differences between groups, but this is all low certainty evidence.

**Overall completeness and applicability of evidence**

Although we identified a large number of studies, many of these did not report, or did not fully report, the primary outcomes of this review: wound healing and infection. Usable data on key outcomes were therefore limited and often unavailable. Only a minority of studies reported enough data to enable us to calculate the most appropriate measure of time-to-event data - a hazard ratio. Where this was not available we were in some cases able to report a mean time to healing or a relative risk of healing for a particular time point. Neither of these measures is ideal and both may give an impression of either an effect or a lack of effect which is not truly present, particularly where the event rate is high.

Usable evidence on infection was also limited, which is disappointing in an area in which infection control is so key. Although a number of studies reported microbiological data, the proportion reporting analysable data on clinical infection was much smaller. Much of the evidence is of low certainty or very low certainty because of indirectness and imprecision.

The geographical distribution of the studies reflected the concentration of disease burden outside of Western high-income countries. Most studies included participants described as having second-degree burns and there were no studies focusing on full-thickness burns, although some studies allowed participants with some area of full-thickness (described as third-degree) injury. Therefore any conclusions that can be drawn from this review are likely to be directly relevant only to participants with second-degree burns limited to TBSA of 40% or lower. Their reliability for other types of burns will be reduced by indirectness.
Quality of the evidence

For most of the comparisons assessed here the evidence relating to key outcomes was assessed as being of low or very low certainty. In some cases this was the result of evidence being at high risk of bias, but in more instances it was a consequence of serious imprecision or inconsistency, or both; in some cases indirectness was an issue due to the use of surrogate outcomes. Although we judged a minority of studies to be at high risk of bias, we judged most to be at unclear risk of bias on several or most domains. Often the fact that there was only a single study available - or only a single study with analysable data - meant that confidence intervals were very wide or fragile, or both, because of the small number of participants represented. A number of studies adopted an intra-individual design (see Potential biases in the review process) and it was unclear whether this was taken into consideration in the analyses. There is, therefore, a high level of uncertainty around many of the findings. We note that this is the case although we adopted a conservative approach to downgrading for risk of bias in our GRADE assessments, and only downgraded where there was judged to be a high risk of bias: we did not downgrade for risk of bias where one or more domains had an unclear risk of bias.

Potential biases in the review process

Study design

A number of studies adopted an intra-individual (split-body) approach analogous to the 'split-mouth' design (Lesaffre 2009). These studies have particular issues and, if incorrectly analysed, can produce inaccurate confidence intervals around the estimates of effect. Where there are a number of such studies for a given comparison there is a case for analysing them separately from parallel-group designs. We had failed to anticipate the number of trials with these designs, which were eligible for inclusion in our review, and therefore our approach to handling them is necessarily post-hoc. There were ten trials with this design and it was unclear whether they had accounted for the intra-individual design in their analyses. In most of our analyses there were limited numbers of these studies as they were distributed across the large number of comparisons in the review. Therefore we have adopted a pragmatic and conservative approach: where these studies contributed data to a meta-analysis with at least two other studies, we conducted a post-hoc sensitivity analysis and used the results of that to inform the GRADE assessment if it differed substantively from the primary analysis. Where there was only one additional study in the analysis, we reported both the pooled results and the results of the two trials with different designs separately. Where these studies were present in an analysis but did not contribute weight to it (because of zero events or lack of measures of variance), we noted their presence. In all except one case the sensitivity analysis conducted did not materially affect the estimate of effect or the confidence intervals. In a single case we have downgraded twice rather than once for imprecision because, in the sensitivity analysis excluding a trial with an intra-individual design, the confidence intervals differed from the main analysis in crossing the line of no effect. We are therefore confident that our post-hoc approach to data from these trials is unlikely to have affected the findings of the review, and that fully including the data increases the comprehensiveness of the review.

Language and setting

Eleven of the included studies were reported in languages other than English, with ten in Chinese and one in Portuguese, as were many of the excluded studies (Chinese, German). We therefore do not believe that language bias is likely to be an issue. The included studies were conducted across a wide range of countries. Only around a third (17) of the studies were conducted in Western, high-income countries. The majority were based in low- to middle-income countries, almost all in Asia, where much of the mortality and morbidity burden from burns is concentrated. It therefore seems likely that in this respect participants in the included studies may reflect those with burns world wide.

Funding

The great majority of the included studies did not state how they were funded. Of those where the funding source was clear, five were funded by industry and six by other non-commercial sources; two others reported both types of funding. Where funding sources are not clearly reported, it can be conservative to assume that this may be a source of bias. However, in this case many of the studies were small and of short duration, and it is therefore likely that they may not have received any external funding.

Publication bias

We did not find evidence of publication bias although it remains a possibility that undetected publication bias was present in some analyses. In some comparisons it was clear that the antiseptic treatment was intended as the comparator: the intervention that the trial was designed to evaluate was the non-antibacterial comparator. If either funding or selective publication were leading to the introduction of bias or potential bias, this would mean that trials that favoured antiseptics would be disproportionately likely to be absent. This was not a pattern that we found evidence to support.

Agreements and disagreements with other studies or reviews

There is a current published Cochrane Review of antibiotics for the prevention (prophylaxis) of burn wound infection (Barajas-Nava 2013), while a second Cochrane Review of antibiotics for the treatment of infected burn wounds is now underway (Lu 2016). This review of antiseptics complements these reviews and completes the assessment of evidence for agents with antimicrobial properties in the care of all burn wounds, whether infected or not.

There is some overlap between this review and other Cochrane and non-Cochrane reviews of dressings for partial-thickness burns (Wasiak 2013), and of individual agents with antiseptic properties for all types of wounds (Aziz 2012; Dat 2012; Jull 2015; Storm-Versloot 2010; Vermuelen 2010), however, this review provides a single synthesis of the randomised evidence relating to all antiseptics for any type of burn wound as well as having a more recent search. This, together with
differences in inclusion criteria mean that there are differences in the included studies. It is worth noting that over 30% of the studies in this review were published in 2010 or later. There are also differences in the approach to analysis, with this review deriving hazard ratios to allow evaluation of the ‘chance’ of healing over time for some of the comparisons; this is a more robust measure of the outcome than mean time to healing or the occurrence of healing events at a single time point.

**Authors’ conclusions**

**Implications for practice**

The effect of different treatments in many of the comparisons is unclear: it is often uncertain whether the antiseptics assessed in these (often single, small) trials are associated with any difference in healing, infections, adverse events or other outcomes. The certainty of this evidence is low or very low, primarily due to the high levels of imprecision around the estimates of effect.

In some cases (see **Summary of main results**) there is moderate or high evidence for the comparisons of honey to topical antibiotics or non-antibacterial dressings. This suggested that there is an advantage to the use of honey over the alternative treatments in these comparisons in terms of wound healing. We note that there was very limited reporting of data on pain in the comparisons involving honey. Pain is particularly important in this patient group and has been reported to be a consideration in the use of honey. Practitioners may wish particularly to take the lack of data on this outcome into account, together with the evidence on healing and infection. There is, however, some moderate certainty evidence that pain may be reduced more from baseline in burns treated with Aloe Vera compared with silver sulfadiazine (SSD) and that there may be lower levels of pain in participants treated with cerium nitrate in addition to SSD compared with SSD alone.

Much of the evidence in this review will also need careful consideration by practitioners in order to determine whether it is relevant to their practice. There was a degree of heterogeneity in terms of the age of participants - ranging from very young children to adults. However most of the studies - with some notable exceptions - focused on burns, which were described as, or corresponded to, 'second-degree burns' and most were below 40% TBSA - in some cases very much less than this. In addition some of the comparators used may not be considered by practitioners to be relevant to their clinical work. This is particularly the case for the comparisons involving honey and non-antibacterial dressings. In many cases it is possible that the evidence may be only indirectly relevant to particular patient groups.

In many cases the methods used in the trials were not well described and we are unsure whether they were designed in a way that makes different types of bias unlikely; although we have not downgraded for an unclear risk of bias, we are not confident that it may not be present.

**Implications for research**

There is a surprising paucity of randomised evidence assessing comparisons between some of the principal antiseptic agents - both with each other and with either topical antibiotics or non-antibacterial agents. Many comparisons were represented by a single trial and many trials did not report adequate data on key outcomes. The exception to this is that there are a large number of trials that assess (1) silver-based treatment (mainly dressings) compared with the topical antibiotic SSD and (2) honey compared with alternative treatments including SSD. Very few of these trials, however, are sufficiently clearly reported for us to be completely confident that they were well-conducted. This is also the case for the smaller number of trials available for other comparisons. Most trials were also small, meaning that there is necessarily a high level of imprecision and often inconsistency present in the comparisons to which they contribute. Nine comparisons included only a single small trial. Where more than one trial contributed to the comparison, it was still sometimes the case that primary outcomes were reported by only one trial - this was particularly the case for infection. In some comparisons there was a large difference in the results of trials reporting an outcome; for example in the comparison of wound healing for iodine compared with non-antibacterial treatments. For all these reasons the evidence for most outcomes for most comparisons was assessed as being of low or very low certainty. Even where there was evidence that was assessed as moderate or high certainty, the reporting of the trials was often insufficient for us to be very confident that bias was unlikely.

Given the key importance of infection control as well as wound healing, the lack of evidence on this outcome for many comparisons was particularly striking. In view of this uncertainty and the large number of treatment options with antiseptic properties, the design of future trials should be driven by high priority questions from patients and other decision makers. It is also important for research to ensure that the outcomes that are collected in research studies are those that matter to patients and health professionals; clinical infection and pain may be examples of such outcomes. Where trials are conducted, good practice guidelines must be followed in their design, implementation and reporting. Such trials should be adequately powered to detect differences in time to healing, should use appropriate statistical methods for time-to-event analyses and should include adequate follow-up to allow all participants to heal. Consideration should also be given to enrolment criteria to ensure that trials are relevant to patients with differing levels of burn severity (depth) and extent (proportion of total body surface area).

**Acknowledgements**

The authors would like to acknowledge the contribution to the protocol of peer referees David Margolis, Heather Cleland, Camila Pino, Christine Fyfe and Abimbola Farinde and the copy editor Clare Dooley; and the contributions to the review of peer referees Andrew Jull, Mark Rodgers, Camila Pino and Caitlin Mitchell. They are also grateful to the copy editor, Denise Mitchell.

Declarations of interest

Gill Norman: my employment at the University of Manchester is funded by the National Institute for Health Research (NIHR) UK and focuses on high priority Cochrane Reviews in the prevention and treatment of wounds.

Janice Christie: none known.

Zhenmi Liu: my employment at the University of Manchester is funded by the NIHR (NIHR Research Methods Programme Systematic Review Fellowship NiHR-RMFI-2015-06-52).

Maggie Westby: My employment at the University of Manchester is funded by the NIHR and focuses on high priority Cochrane Reviews in the prevention and treatment of wounds.

Jayne Jeffries: none known.

Thomas Hudson: none known.

Jacky Edwards: none known.

Devi Prasad Mohapatra: none known.

Ibrahim Hassan: none known.

Jo Dumville: I receive research funding from the NIHR for the production of systematic reviews focusing on high priority Cochrane Reviews in the prevention and treatment of wounds. This work was also partly funded by the National Institute for Health Research Collaboration for Leadership in Applied Health Research and Care (NIHR CLAHRC) Greater Manchester.

Andrew Jull (peer reviewer) is the author of a published Cochrane Review investigating the effect of honey on wounds Jull 2015, which was the source of some of the raw data for this review.

Differences between protocol and review

29 / 205
The protocol did not address a particular study design which several of our included studies employed: the intra-individual design where burns or burn areas were randomised to different treatments. The closest parallel to this is the 'split-mouth' design. It was not clear that the analyses of these studies took the design into account. We have adopted the approach of including these studies in our meta-analyses but undertaking post-hoc sensitivity analyses to explore the impact of including them. Where there was a substantive difference between the results of the principal analysis and the sensitivity analysis we were conservative and used the results of the sensitivity analysis to inform the GRADE assessment.

Due to the large number of comparisons included in the review we did not produce a 'Summary of findings' table for every outcome for every comparison, in order to keep them to a manageable size. Instead, where comparisons had limited available data for prespecified outcomes we presented these data together with GRADE judgements in an additional table. Due to the large number of comparisons that only reported mean time to healing (where all wounds healed) as a measure of healing, we included this in both 'Summary of findings' tables and additional tables of GRADE judgements.

Comment: no report of VAS or resource use, which were listed as assessed outcomes. Also many outcomes had to be extrapolated from graphs |
| Other bias                         | Unclear risk       | No evidence of other sources of bias but reporting insufficient to be certain |

*Adhya 2015*
### Methods
- Country where data collected: India
- Parallel-group RCT (stratified randomisation)
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 4 weeks for most outcomes, until epithelialisation for wound healing

### Participants
- Inclusion criteria: second-degree burns, 20% to 60% TBSA
- Exclusion criteria: superficial (first-degree) or full-thickness (third-degree burns); pregnancy; "significant" comorbidities: pre-existing heart disease; renal disease; diabetes
- Participants: 163 hospital patients (unclear if inpatient or outpatient)
- Mean age (years): 27.4 vs. 31.8
- Male participants: 29/52 vs 25/52
- Burn type: NR
- Burn degree and size (%TBSA): mix of 20% -40% TBSA (12 vs 15 superficial; 13 vs 17 deep dermal) and > 40%-60% TBSA (10 vs 6 superficial; 14 vs 14 deep dermal) (also stratified in the analysis)
- Burn location: NR
- Note participant characteristic data refers to analysed participants not the total number randomised (substantial difference)

### Interventions
- Intervention arm 1: nano-crystalline silver hydrogel (50 ppm), applied topically on alternate days. N = 52
- Intervention arm 2; SSD cream (DISILVA, 1%), applied topically on alternate days. N = 52
- Cointerventions: unspecified dressing

### Outcomes
- Primary outcome: wound healing - proportion of wounds completely healed by 4 weeks (reported only for deep dermal burns)
- Primary outcome: wound healing - time (days) to complete wound healing

### Notes
- Funding: Department of Science & Technology, West Bengal

| Random sequence generation       | Unclear risk       | "Simple randomization sequence was generated by computer software"  
Comment: unclear what “simple” means in this context but computer-generated randomisation sequences generally regarded as low risk |
| Allocation concealment           | Unclear risk       | "After allocation of patients into two different groups, SSD and AgNP gel were administered topically…”  
Comment: no detail on allocation concealment |
| Blinding of outcome assessment   | High risk          | "this study was designed as an open-label prospective, parallel group, randomized controlled trial.....Clinical assessments of burn wound were done on every week till 4th week and on completion of treatment.”  
Comment: open label trial with no mention of blinding assessors |
| Incomplete outcome data          | High risk          | "Data for evaluation were obtained for 54 patients on SSD (2° deep-dermal cases 27) and 52 (2° deep-dermal cases 31) on AgNP treatment”  
Comment: 163 randomised, 57 lost to follow-up. Similar numbers in each arm (30 vs. 27) but no reasons given |
| Selective reporting              | Unclear risk       | "As shown in Table 4, considering deep-dermal burn wounds only, the differences in treatment outcome at 4 weeks was statistically highly significant ($P = 0.003$) in favor of AgNP treatment. However, at 4 weeks, only 4 cases in AgNP arm had achieved complete wound healing compared to none in the SSD arm, and this was not a statistically significant difference [Table 5]. However, 25 had achieved 50% wound healing compared to 13 on SSD, and this was statistically significant ($P = 0.001$)."  
Comment: proportion of wounds healed completely by 4 weeks given for deep dermal wounds only. No explanation of why analysis would be stratified |
| Other bias                       | Low risk           | Comment: no other issues identified, but reporting insufficient to be certain |

| Random sequence generation (selection bias) | Unclear risk       | Quote “after taking consent patients were randomly attributed to two study groups”  
Comment: no information on how randomisation sequence was derived |
| Allocation concealment (selection bias)   | Unclear risk       | Quote “after taking consent patients were randomly attributed to two study groups”  
Comment: no information on whether allocation of study treatment was concealed |
| Blinding of outcome assessment (detection bias) | Unclear risk       | Quote: "Wound was assessed at third and seventh day and at the time of completion of study. Final outcome was measured after 2 months of follow-up, in terms of complete and incomplete recovery."  
Comment: no information on whether assessment was blinded |
| Incomplete outcome data (attrition bias)  | Low risk           | Comment: no specific quote but outcome data on time to healing reported for all 78 randomised participants |
| Selective reporting (reporting bias)      | Unclear risk       | Comment: no specific quote but outcomes other than "complete recovery" were not prespecified so it is unclear whether all outcomes assessed were fully reported |
| Other bias                                | Unclear risk       | Comment: no specific quote, no evidence of other bias but reporting insufficient to be certain |

Bangroo 2005
| Methods | Country where data collected: India  
Parallel group RCT  
Unit of randomisation: participant  
Unit of analysis: participant  
Duration: NR |
|----------|--------------------------------------------------|
| Participants | Inclusion criteria: < 12 years old, superficial thermal burn, < 50% TBSA  
Exclusion criteria: NR  
Participants: 64 hospital patients (children)  
Mean age (years): NR  
Male participants: 23/32 vs 25/32  
Burn type: 56 wet burns, 8 dry burns  
Burn degree: NR/NA  
Burn size (%TBSA): < 10% 5 vs 3; 11%-20% 2 vs 5; 21%-30% 7 vs 8; 31%-40% 16 vs 15; 41%-50% 2 vs 1  
Burn location: 12 facial, 20 extremities, 21 trunk and abdomen |
| Interventions | Intervention arm 1: honey dressing (changed twice daily) N = 32  
Intervention arm 2: SSD (dressing changed twice daily) N = 32  
Cointervention: Thorough bath, twice daily with tap water and soap; followed by sponging and peeling away dead skin. |
| Outcomes | Primary outcome: Wound healing (mean time to healing)  
Secondary outcome: Adverse events |
| Notes | Funding NR |

**Risk of bias table**
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation (selection bias)   | Unclear risk       | Quote: "Randomly, alteration [sic] was used of permuted 20 sub-blocks of sizes from 1-3 for deep partial thickness burns group and 25 sub-blocs of the same size for the superficial partial burn groups.”  
Comment: does not state how randomisation sequence was derived |
| Allocation concealment (selection bias)       | Unclear risk       | Quote: "The allocation was carried out by the staff of outpatient reception desk of the Clinic. Patient Envelopes were provided for patients requiring treatment allocation in each group. These were numbered sequentially and a list was provided with the envelopes and completed with the trial number and patient name. The date when the envelope was opened (i.e., the date of randomization) was added.”  
Comment: the envelopes were sequentially numbered but not said to be sealed or opaque, and it’s not known what the reception staff knew about the participants |
| Blinding of outcome assessment (detection bias)| Low risk           | Quote: "Blinding was made only for persons evaluating treatment outcomes in order to eliminate classification bias.” This was not the case for pain “Blinding the treatments was not possible because Povidone iodine has a characteristic color and odor”  
Comment: outcome assessors were blinded to treatment allocation except for pain outcomes where participants were the assessors |
| Incomplete outcome data (attrition bias)      | Low risk           | Quote: "211 (214 randomized) patients, aged between 18-75 years were prospectively selected. Three patients were excluded because of violation of the inclusion criteria (need of surgical operation). The flow of the participants is described in Figure 1,...We did have loss of contact for the pain measurement (9th day and after) for 3 patients recovered earlier than 8th day (1 for the MEBO group and 2 for the old therapy group). These censored observations were imputed by the Method of Last Observation Carried Forward, with decreased risk of bias because the censoring occurred near the end of the follow-up period”  
Comment: Figure one shows all randomised participants included in analysis; the number of participants affected by censoring was low. |
| Selective reporting (reporting bias)          | Low risk           | Comment: no specific quote but primary outcomes and other outcomes specified and reported fully |
| Other bias                                    | Low risk           | Comment: no specific quote but no evidence of other sources of bias and detailed reporting of methods |

Caruso 2006
Country where data collected: USA
Parallel-group RCT (stratified by TBSA and age)
Unit of randomisation: participant
Unit of analysis: participant
Duration: 21 days

Inclusion criteria: age ≥ 2 months; superficial, mid-dermal, or mixed partial-thickness burns, 5%-40% TBSA, within 36 h of enrolment. Randomisation stratified by TBSA (5%-20% or > 20% -40%) and age (0-3 years or ≥ 4 years)

Exclusion criteria: pregnancy; electrical, chemical, or frostbite burns; areas of burn likely to require excision/grafting; antibiotic use in 2 days prior to burn injury; evidence of inhalation injury; fractures and/or neurological injury.

Participants: 84 hospital or clinic outpatients (unclear if some inpatients also included)
Mean age (years): 29.4 vs 24.0 years
Male participants: 27/42 vs 30/40
Burn type: scald 27/42 vs 18/40; flash 9/42 vs 13/40; flame 4/42 vs 8/40; contact, 0 vs 1; other 2 vs 0
Burn degree: superficial and mid-dermal (N = NR)
Burn size (%TBSA): 12.0% vs 10.8% (superficial 4.8% vs 4.2%; mid-dermal BSA 8.8% vs. 8.1%)
Burn location: NR

Intervention arm 1: silver hydrofibre dressing (AQUACEL Ag Hydrofiber, 1.2% weight ionic silver). Dressing overlapped wounds by 4-5 cm. Applied in hospital/clinic on day 1 and every 2-3 days for 21 days. Dressing covered with gauze and retention dressings. (N = 42)

Intervention arm 2: SSD cream (Silvadene, 1%). 1/16” (1.6 mm) thick application. Outer dressing and dressing changes per package insert but “at least once daily”. Home dressing changes permitted between clinic visits. (N = 42)

Cointerventions: procedural medications & opiates where indicated

Primary outcome: wound healing (proportion of participants with full epithelialisation)
Primary outcome: infection
Secondary outcome: resource use (frequency of dressing changes)
Secondary outcome: pain (VAS)

Notes: Patient characteristic data refers to participants included in analysis, not numbers randomised (2 participants from 1 group excluded)
Funding: ConvaTec, a Bristol-Myers Squibb company (manufacturer of silver dressing)
<table>

</tr>
</thead>
<tbody>
<tr>
<td>Random sequence generation (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: “Patients were assigned randomly to a protocol of care that included either AQUACEL® Ag dressing or silver sulfadiazine. The randomization schedule was stratified by extent of burns (5% to 20% or 20% to 40% of TBSA) and age (0–3 years or 4 years and older)” Comment: no details on how randomisation schedule was produced</td>
</tr>
<tr>
<td>Allocation concealment (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: “Patients were assigned randomly to a protocol of care that included either AQUACEL® Ag dressing or silver sulfadiazine” Comment: no information on allocation concealment is mentioned</td>
</tr>
<tr>
<td>Blinding of outcome assessment (detection bias)</td>
<td>High risk</td>
<td>Quote: “Study treatment was not blinded”; “Outcomes were measured at every in-clinic dressing change until study completion or premature study discontinuation” Comment: Blinding in relation to clinical outcome assessment was not mentioned. Healthcare cost analysis was performed by an independent group but no mention of blinding. Participants weren't blinded and outcomes were assessed at in-clinic dressing change when group assignment would have been apparent based on the dressing.</td>
</tr>
<tr>
<td>Incomplete outcome data (attrition bias)</td>
<td>Low risk</td>
<td>Quote: “In the AQUACEL® Ag dressing group, all 42 patients were included in the safety and intent-to-treat analyses. In the silver sulfadiazine group, 40 of 42 patients were included in the safety and intent-to-treat analyses because 2 patients did not receive study treatment. Comment: although there was incomplete data for pain and long-term follow-up all participants were accounted for in the ITT wound healing analysis</td>
</tr>
<tr>
<td>Selective reporting (reporting bias)</td>
<td>Unclear risk</td>
<td>Comment: No direct quote but the outcomes to be assessed were not prespecified in the methods so it is unclear whether they were fully reported</td>
</tr>
<tr>
<td>Other bias</td>
<td>Unclear risk</td>
<td>Comment: No direct quote but no evidence of other sources of bias although high levels of manufacturer involvement were noted</td>
</tr>

*Chen 2006*
Methods

Country where data collected: China
Parallel-group RCT
Unit of randomisation: participant
Unit of analysis: participant
Duration: NR (until healing)

Participants

Inclusion criteria: second-degree burn wounds (superficial or deep); in hospital within 0.5-12 h
Exclusion criteria: NR
Participants: 191 hospital patients
Mean age (years): (35 ± 12) vs (30 ± 9) vs (32 ± 11)
Male participants: 42/65 vs 36/63 vs 35/63
Burn type: NR
Burn degree: superficial 31 vs 33 vs 32; deep 34 vs 30 vs 31
Burn size (%TBSA): superficial: 38.3 ± 18.1 vs 22.5 ± 10.2 vs 28.3 ± 8.6; deep 10.1 ± 2.2 vs 6.3 ± 3.2 vs 8.2 ± 1.6
Burn location: NR

Interventions

Intervention arm 1: silver nanoparticle dressing, changed every day (N = 65)
Intervention arm 2: 1% SSD cream, changed every day (N = 63)
Intervention arm 3: Vaseline gauze, changed every day (N = 63)
Cointerventions: wounds cleaned with 0.5% iodophor

Outcomes

Primary outcome: wound healing (mean time to wound healing)

De Gracia 2001
| **Methods** | Country where data collected: Philippines  
Parallel-group RCT  
Unit of randomisation: participant  
Unit of analysis: participant  
Duration: NR (until healing of partial-thickness burns and readiness for skin grafting in full-thickness burns) |
|---|---|
| **Participants** | Inclusion criteria: aged > 4 months with TBSA > 15%, admitted within 24 h of burn injury  
Exclusion criteria: inhalation injury, known hypersensitivity to sulfonamides, known methemoglobinemia during the pre-burn period  
Participants: 60 participants with moderate or severe burns  
Mean age (years): 30 (11.5) vs 24 (14.6)  
Male participants: 16/30 vs 20/30  
Burn type: NR  
Burn degree: partial and full-thickness  
Burn size (%TBSA): partial-thickness 22% vs 30%; full-thickness 5.6% vs 2.1%  
Burn location: face, perineum, trunk, extremities (proportions not reported) |
| **Interventions** | Intervention arm 1: SSD (Flammazine) changed 2-3 times daily for open dressings on face or perineum; daily on trunk and extremities (closed dressings)  
Intervention arm 2: SSD plus cerium nitrate (Flammacerium) changed 2-3 times daily for open dressings on face or perineum; daily on trunk and extremities (closed dressings)  
Cointerventions: fluid and electrolyte resuscitation, wound cleansing with skin cleanser soap and water or normal saline |
| **Outcomes** | Primary outcome: wound healing (partial-thickness burns only)  
Primary outcome: infection and septicaemia  
Secondary outcome: mortality  
Secondary outcome: adverse events |
| **Notes** | Data extraction and 'Risk of bias' assessment undertaken by translators from Portuguese

Glat 2009
## Methods
- Country where data collected: USA
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 21 days +

## Participants
- Inclusion criteria: age: 2 months–18 years; enrolment: < 36 h post-injury; burn severity: superficial to mid-dermal, TBSA 1%-40%
- Exclusion criteria: electrical or chemical burns; deep or full-thickness burns; previous antimicrobial or enzymatic debridement; death likely within study period; enrolment in a previous study; pregnancy
- Participants: 24 children attending a paediatric hospital; mixture of inpatients and outpatients
- Mean age (months): 22.8 vs 43.0
- Burn size (%TBSA): TBSA 1%-10% (stated as being “comparable” between treatment arms)
- All other characteristics NR

## Interventions
- Arm 1: SSD cream (Silvadene, 10 mg) 1/16” (1.6 mm) thickness every 2-3 days
- Arm 2: silver hydrogel (SilvaSorb), 1/16” (1.6 mm) thickness every 2-3 days
- Cointerventions: initial blister fluid drainage. Cream/gel covered with non-adherent dressing, rolled gauze and Elasti-net. Participants or parents were allowed to change wound dressings in outpatient cases.

## Outcomes
- Primary outcome: wound healing: time to complete wound healing (mean time to (full) re-epithelialisation)
- Primary outcome: wound healing: proportion of wounds completely healed during follow-up ((full) re-epithelialisation at 21 days
- Secondary outcome: adverse events
- Secondary outcome: resource use (number of dressing chances)
- Secondary outcome: pain (during dressing changes, measured using the Wong-Baker Faces Pain Scale/observational pain assessment scale in infants or toddlers)

## Notes
- Funding: Drexel University School of Medicine by Medline Industries

Risk of bias table
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation (selection bias) | Unclear risk       | Quote: "A total of 213 patients who attended the Accident and Emergency Department, Royal Victoria Infirmary, Newcastle upon Tyne with partial skin thickness burns were entered into a prospective randomized (random permuted block allocation) single blind trial."  
Comment: insufficient information on how the randomisation sequence was derived. |
| Allocation concealment (selection bias)  | Unclear risk       | Quote: "A total of 213 patients who attended the Accident and Emergency Department, Royal Victoria Infirmary, Newcastle upon Tyne with partial skin thickness burns were entered into a prospective randomized (random permuted block allocation) single blind trial."  
Comment: no information on whether the allocation was adequately concealed |
| Blinding of outcome assessment (detection bias) | Unclear risk       | Quote: "All patients were reviewed in the clinic 3 days later in the first instance and subsequently every 5 days. A data sheet was prepared for each patient and data recorded during the change of dressing according to a predetermined grading system relating to the description of the wound and/or dressings and clinical parameters".  
Comment: no information on whether outcome assessors were blinded to treatment allocation |
| Incomplete outcome data (attrition bias)  | Unclear risk       | Comment: no specific quote but no information on whether all patients were involved in most analyses; children were specifically excluded from assessment of pain and a total of 24% of participants were not included for this outcome |
| Selective reporting (reporting bias)      | High risk          | Quote: "Mean scores for pain and wound characteristics were calculated for each patient."  
Comment: it was not clear whether these (and dressing performance) were planned as the only assessed outcomes; the outcomes that they planned to assess appear to be listed on the datasheet (fig 1) - this includes healing, which is not properly reported (e.g. "there were no differences in the other parameters") |
| Other bias                                | Unclear risk       | Comment: no specific quote, no evidence of other sources of bias but reporting insufficient to be certain                                                                                                             |
## Methods
Country where data collected: UK
Parallel-group RCT
Unit of randomisation: participant
Unit of analysis: participant
Duration: Up to 14 days

## Participants
Inclusion criteria: people with partial-thickness burns covering < 10% TBSA
Exclusion criteria: burns to face and hands
Participants: 32 individuals with burns (no further information)
Mean age (years): 2.6 (includes 0 adults) versus 20.6 (includes 5 adults)
Male participants: NR
Burn type: scald 25, flame 6, contact 1 (numbers approximately equal between groups)
Burn degree: partial-thickness
Burn size (%TBSA): $1.8 \pm 0.8$ vs $2.3 \pm 0.6$
Burn location: NR

## Interventions
Intervention arm 1: silver-impregnated porcine xenograft (E-Z Derm) $N = 16$
Intervention arm 2: petroleum gauze (Jelonet) $N = 16$
Cointerventions: NR

## Outcomes
Primary outcome: wound healing
Secondary outcome: adverse events (need for surgery)

## Notes
Funding NR

*Homann 2007*
### Methods
- **Country where data collected:** Germany
- **RCT with intra-individual design**
- **Unit of randomisation:** burn
- **Unit of analysis:** burn
- **Duration:** 21 days

### Participants
- **Inclusion criteria:** 2 partial-thickness burn wounds of comparable size, location and prior treatment, ≤ 3 days from injury; TBSA ≤ 50%; wound area between 36 cm² - 300 cm²; upper body injuries needed to both occur on either ventral or dorsal side
- **Exclusion criteria:** infected wounds at study onset, wounds in the axillary or inguinal region, deep body folds or a distinctive adipose tissue region
- **Participants:** 43 participants with 2 comparable burns
- **Mean age (years):** NR
- **Male participants:** NR
- **Burn type:** NR
- **Burn degree:** partial-thickness
- **Burn size (%TBSA):** 11.1 ± 7.7 (79.2 cm² vs 77.3 cm²)
- **Burn location:** NR

### Interventions
- **Intervention arm 1:** polyvinylpyrrolidone iodine liposome hydrogel (Repithel) (3% PVP-iodine, 3% phospholipin 90 H liposome). Applied once daily as 2 mm layer covered with paraffin gauze dressing. N = 43
- **Intervention arm 2:** SSD (10 mg/g). Applied once daily as 2 mm layer covered with paraffin gauze dressing. N = 43
- **Cointerventions:** no additional topical treatments

### Outcomes
- **Primary outcome:** wound healing
- **Primary outcome:** infection
- **Secondary outcome:** adverse events

### Notes
- **Funding:** Mundipharma GmbH (manufacturer)
- This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

**Risk of bias table**
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random sequence generation (selection bias)</td>
<td>Low risk</td>
<td>Quote: “The randomization list was prepared by the statistics department from Mundipharma GmbH, using the EDP program Rancode 3.6.” Comment: computer-generated randomisation list is classed as low in terms of risk-of-bias.</td>
</tr>
<tr>
<td>Allocation concealment (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: “After written informed consent was obtained, patients were enrolled and the 2 burn wounds to be assessed were randomized to treatment with the liposome PVP-I hydrogel Repithel or the silver-sulfadiazine cream Flammazine.” Comment: no explicit mention of allocation concealment</td>
</tr>
<tr>
<td>Blinding of outcome assessment (detection bias)</td>
<td>High risk</td>
<td>Quote: “A limitation to this study is the fact that, due to the characteristic coloring of PVP-I, this was not a blinded study.” Comment: unblinded study</td>
</tr>
<tr>
<td>Incomplete outcome data (attrition bias)</td>
<td>Unclear risk</td>
<td>Quote: “Forty-three patients comprised the full analysis set (intent-to-treat) and 39 patients completed the study per protocol. Protocol violations were wounds older than 3 days in 2 patients and lack of comparability of wounds or a full-thickness (degree IIb/III) burn wound in 1 patient each.” Comment: no unexplained loss to follow-up</td>
</tr>
<tr>
<td>Selective reporting (reporting bias)</td>
<td>Unclear risk</td>
<td>Quote: “The clinical assessment of study wounds included inflammation (secretion, reddening, coating) and healing tendency (very good, good, moderate, none).” Comment: some uncertainty about the above statement – the word “included” implies there may possibly have been more outcomes assessed.</td>
</tr>
<tr>
<td>Other bias</td>
<td>Unclear risk</td>
<td>Comment: it was unclear whether the analysis took account of the intra-individual design</td>
</tr>
</tbody>
</table>

*Huang 2007*
### Methods
Country where data collected: China  
Parallel-group RCT (multicentre)  
Unit of randomisation: participant  
Unit of analysis: burn  
Duration: 20 days

### Participants
Inclusion criteria: men and women aged 18-65 years with burn wounds unhealed 3 weeks after injury (residual burn wounds)  
Exclusion criteria: serious complications of heart, liver, kidney or blood system (blood production or bleeding issues); serious complications, shock or serious systemic infection; uncontrolled diabetes, pregnancy or breast feeding, allergy to solver ions; other reason unable to complete observation period  
Participants: 111 participants randomised, 98 analysed with 166 burns  
Mean age (years): NR  
Male participants: NR  
Burn type: NR (residual wound)  
Burn degree: NR  
Burn size (%TBSA): NR

### Interventions
Intervention arm 1: nanocrystalline silver dressing (Acticoat) changed once daily where redness, swelling and high levels of exudate, otherwise every 3 days. Auxilliary dressing over intervention dressing. (83 burns analysed)  
Intervention arm 2: SSD (5 g per 80 cm²) changed once daily. (83 burns analysed)  
Cointerventions: washing/rinsing of wounds with sterile water

### Outcomes
Primary outcome: wound healing  
Primary outcome: change in infection status  
Secondary outcome: adverse events

### Notes
Data extracted from English language publication; 2 additional Chinese language publications  
Funding NR  
This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

  - **55 / 205**
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random sequence generation (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: &quot;A multi-center, randomized experimental design is adopted, with blinding and positive parallel control. The clinical trial was done in four burn centers throughout the country at the same time with the same experimental design. The observing doctor hands out the dressing to every patient according to the time that they come to the hospital and to a randomized serial number.” Comment: no information on how the randomisation sequence was derived</td>
</tr>
<tr>
<td>Allocation concealment (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: &quot;A multi-center, randomized experimental design is adopted, with blinding and positive parallel control. The clinical trial was done in four burn centers throughout the country at the same time with the same experimental design. The observing doctor hands out the dressing to every patient according to the time that they come to the hospital and to a randomized serial number.” Comment: insufficient information on whether the allocation sequence was adequately concealed</td>
</tr>
<tr>
<td>Blinding of outcome assessment (detection bias)</td>
<td>Unclear risk</td>
<td>Quote: &quot;Standards for the healing of wound: the wound healed was determined by inspection by two doctors.” Comment: no information on whether the outcome assessors were blinded (although the trial is described as blinded)</td>
</tr>
<tr>
<td>Incomplete outcome data (attrition bias)</td>
<td>Low risk</td>
<td>Quote: &quot;Altogether 111 patients were enrolled in this group, in the process of the trial, 13 patients were dropped out of the study. Among them two patients were dropped out because of silver allergy. Eight were removed because they left to their local clinic before the wound healed, therefore we do not have their related records. Three patients were dropped because of liver dysfunction. The remaining 98 patients who were included in the statistical analysis had altogether 166 residual wounds” Comment: 13/111 participants were not included in the analysis. The event rate was high so although there is potential for differential missing data the impact on the effect estimate was probably small.</td>
</tr>
<tr>
<td>Selective reporting (reporting bias)</td>
<td>Unclear risk</td>
<td>Quote: &quot;This study is to investigate the efficacy and safety of nanocrystalline silver (Acticoat) in the treatment of burn wounds, and to assess the clinical value of this dressing.” Comment: no specification of how efficacy and safety was to be assessed so difficult to determine if all planned outcomes were reported. However a statistical analysis for wound healing rate was pre-specified and presented</td>
</tr>
<tr>
<td>Other bias</td>
<td>High risk</td>
<td>Comment: unit of analysis issues arising from randomisation at the participant level and analysis at the level of the burn (multiple burns for some participants)</td>
</tr>
</tbody>
</table>

Inman 1984
### Methods
- Country where data collected: Canada
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: NR (duration of healing up to mean 26 days)

### Participants
- Inclusion criteria: age > 1 year; full-thickness burns; < 24 h post injury
- Exclusion criteria: prior topical antibiotic treatment, pregnant, allergic to sulfa drugs
- Participants: 121 analysed, N randomised unclear
- Mean age (years): 31 ± 21 vs 33 ± 25
- Male participants: NR
- Burn type: flame 35 vs 38; scald 8 vs 20; electrical contact 3 vs 1; other 8 vs 8
- Burn degree: full-thickness
- Burn size (%TBSA): full-thickness 13 ± 16 vs 10 ± 11
- Burn location: perineal 10 vs 9 (9 vs 5 full-thickness); inhalation injury 10 vs 16 (ventilator 7 vs 9)

### Interventions
- Intervention arm 1: SSD (1%) plus chlorhexidine digluconate (0.2%) cream (Silvazine); “buttered on to wound and/or wound dressed with "buttered" cotton gauze. 54 participants
- Intervention arm 2: SSD (1%) (Flamazine) buttered on to wound and/or wound dressed with "buttered" cotton gauze. 67 participants
- Cointerventions: antibiotics as appropriate; daily bathing with non-antibacterial soap and wound debridement, wound excision as appropriate

### Outcomes
- Primary outcome: wound healing
- Primary outcome: infection
- Secondary outcome: mortality (overall, infection-related)
- Secondary outcome: adverse events

### Notes
- A list of exclusions are presented that appear likely to account for post-randomisation withdrawals, number randomised unclear
- Funding: British Columbia Professional Firefighters Association; Smith & Nephew Canada
- An additional paper (Snelling 1991) reported additional participants but it appeared that these participants were not randomised to the intervention groups and so are not reported here. The reference is provided as a secondary citation for the study.
- Funding: British Columbia Professional Firefighters Association and Smith and Nephew Canada

### Methods
- **Country where data collected:** China
- **Parallel-group RCT**
- **Unit of randomisation:** participant
- **Unit of analysis:** participant (one wound per participant)
- **Duration:** until healed

### Participants
- **Inclusion criteria:**
  - Fresh burn wound; total burn 10%-20% TBSA; no other serious injury; no other major diseases (including cancer, brain disease; heart disease; kidney disease; haematological system disease; and infection); admitted to hospital within 24 h of injury
  - Exclusion criteria: NR
- **Participants:** 76 hospital patients
- **Male/female:** 44/76 (24/38 vs 20/38)
- **Age:** 18-58 (36.8 ± 14.2) (36.5 ± 11.8 vs 36.8 ± 13.2)
- **%TBSA:** 15.2 (4.3)
- **Burn degree:** superficial: 19 vs 22; deep 19 vs 16
- **All burns were located around knee areas**

### Interventions
- **Intervention arm 1:** nano-silver dressing (N = 38)
- **Intervention arm 2:** ordinary sterile gauze (N = 38)
- **Co-interventions:** human epidermal growth factor was coated on the surface of the wound; dressing was changed every other day

### Outcomes
- **Primary outcome:** wound completely healed
- **Primary outcome:** infection - bacterial positive rate at different time points
- **Secondary outcome:** adverse events; scar hyperplasia

### Notes
- **Paper in Chinese; data extraction and ‘Risk of bias’ assessment performed by one review author**

Methods

Country where data collected: Iran
Parallel-group RCT
Unit of randomisation: participant
Unit of analysis: participant
Duration: 3 months' follow-up

Participants

Inclusion criteria: partial-thickness (superficial thermal) burn, < 40% TBSA
Exclusion criteria: NR
Participants: 100 hospital patients
Mean age (years): 25.2 vs 26.4
Male participants: 23 vs 25
Burn type: flame 43 vs 39; scald 7 vs 11
Burn degree: NR
Burn size (%TBSA): 14.5 (10-40) vs 15.6 (10.5-40)
Burn location: NR

Interventions

Intervention arm 1: honey applied in quantity 16 mL-30 mL on alternate days after saline wash. Wound covered with dry gauze
Intervention arm 2: mafenide acetate-impregnated gauze over wound after saline wash. Changed daily.
Cointerventions: wound cleansing with saline; 1% lidocaine before biopsy

Outcomes

Primary outcome: wound healing
Primary outcome: infection

Notes

Funding: NR

### Methods
- Country where data collected: Pakistan
- Parallel-group RCT (intra-individual)
- Unit of randomisation: burn
- Unit of analysis: burn
- Duration: NR

### Participants
- Inclusion criteria: partial-thickness burns in 2 different parts of the body (same site, e.g. right and left abdomen) occurred within 24 h of treatment initiation. TBSA < 40%
- Exclusion criteria: diabetes, pregnancy, immunodeficiency, kidney diseases; electrical and chemical burns
- Participants: 150 hospital patients
- Mean age (years): 28 ± 16
- Male participants: 67/150
- Burn type: NR
- Burn degree: NR
- Burn size (%TBSA): 22.7 ± 8.5 (10-38)
- Burn location: NR but same site/equivalent

### Interventions
- Intervention arm 1: honey applied directly to wound twice daily; dressing changed twice daily
- Intervention arm 2: SSD applied daily
- Cointerventions: fluid resuscitation, oral nutrition, occasional IV infusion of amino acids and blood products

### Outcomes
- Primary outcome: wound healing
- Primary outcome: infection

### Notes
- Funding: NR
- This was a “split-body” or “intra-individual” design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

*Mashhood 2006*
### Methods
- Country where data collected: Pakistan
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 6 weeks' treatment; follow-up at 6 months

### Participants
- Inclusion criteria: superficial and partial-thickness burns, TBSA < 15%
- Exclusion criteria: deep burns; any medical illness beginning before or after injury
- Participants: 50 surgical hospital outpatients
- Mean age (years): 27.4
- Male participants: NR (both men and women were included)
- Burn type: NR
- Burn degree: NR
- Burn size (%TBSA): NR
- Burn location: NR

### Interventions
- Intervention arm 1: pure honey applied once daily after wound cleansing with normal saline. N = 25
- Intervention arm 2: 1% SSD cream once daily. N = 25
- Cointerventions: wound cleansing with normal saline; sterile gauze dressings

### Outcomes
- Primary outcome: wound healing
- Secondary outcome: pain
- Secondary outcome: costs
- Secondary outcome: adverse events

### Notes
- Funding NR

### Methods
- Country where data collected: Iran
- Intra-individual RCT
- Unit of randomisation: burn
- Unit of analysis: burn
- Duration: 30 days

### Participants
- Inclusion criteria: aged 16–65 years, diagnosed by the same expert emergency burn physician based on the presentation of two same sites of second-degree burns. The burn should have occurred within 24 h before the beginning of treatment, second-degree burn on 2 sides of the same person's body, and with < 15% TBSA
- Exclusion criteria: People with epilepsy, diabetes, immunodeficiency disease, electrical and chemical burns, known allergy and sensitivity to either AEO or SSD, or pregnant women were excluded from the study
- Participants: 49 randomised; 45 analysed
- Mean age (years): 39.9 (SD 15.6)
- Male participants: NR but "most participants were women"
- Burn type: scalds 30; flame 14; contact 1 (analysed participants only)
- Burn degree: second-degree
- Burn size (%TBSA): 3.7 (SD 2.4; range 1-13) (analysed participants only)
- Burn location: 44% involved lower limbs (analysed participants only)

### Interventions
- Intervention arm 1: *Arnebia euchroma* ointment (AEO)
- Intervention arms 2: SSD
- Cointerventions: after admission and primary preparation, the wounds were washed with normal saline or sterile water and dried with sterile gases

### Outcomes
- Primary outcome: proportion of wounds healed at day 13 and mean time to wound healing (re-epithelialisation)
- Primary outcome: signs of clinical infection rated on 6-point scale from 0 = absent to 5 = all components present
- Secondary outcome: adverse events defined as erythema, edema, infection, inflammation, and general wound appearance
- Secondary outcome: pain and itching during first 15 minutes of dressing change measured using a 10-point VAS

### Notes
- Funding: grant (118-92) from Mazandaran University of Medical Sciences, Sari, Iran
- This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

<tbody>
<tr>
<td>Random sequence generation (selection bias)</td>
<td>Low risk</td>
<td>Quote: &quot;These areas were randomly assigned to AEO treatment and the opposite site was treated with conventional treatment with SSD cream. A simple coin-based randomization was performed for each patient after enrolment by the blinded staff nurse.&quot; Comment: the randomisation sequence was generated by an acceptable method</td>
</tr>
<tr>
<td>Allocation concealment (selection bias)</td>
<td>Unclear risk</td>
<td>Quote: &quot;These areas were randomly assigned to AEO treatment and the opposite site was treated with conventional treatment with SSD cream. A simple coin-based randomization was performed for each patient after enrolment by the blinded staff nurse.&quot; Comment: not clear whether the allocation sequence was adequately concealed</td>
</tr>
<tr>
<td>Blinding of outcome assessment (detection bias)</td>
<td>Low risk</td>
<td>Quote: &quot;The general condition of the wound areas were first observed and evaluated by the expert emergency burn physician and the Burn unit special nurse prior to utilization of topical agents. Thereafter, before each dressing, the wounds were assessed by same team who were unaware of the assigned treatment to each side and the ointment applied on the wounds for treatment.&quot; Comment: appears that outcome assessment was performed by individuals blinded to treatment allocation and separate from those applying dressings</td>
</tr>
<tr>
<td>Incomplete outcome data (attrition bias)</td>
<td>Low risk</td>
<td>Quote: &quot;a total of 51 eligible patients were registered. Forty-nine of them signed the consent form and were randomly allocated sequentially to the two sides and two treatment groups. Four patients were lost to follow up. Therefore, 45 patient's results were eligible for data analysis..... In addition, 1 patient in both groups needed bilateral skin graft on the day of 11th according to the plastic surgeon's decision. Furthermore, 2 patients in the SSD group needed skin graft from days 11–14, but their treatment area on the opposite area with AEO healed after 5 and 7 days, respectively&quot; Comment: of the 49 randomised participants 4 were not included in the analysis; each participant was lost from both groups equally; all other participants' data were included in the analysis for each group</td>
</tr>
<tr>
<td>Selective reporting (reporting bias)</td>
<td>Unclear risk</td>
<td>Comment: the outcomes to be assessed were not defined in the methods section so it is not clear whether all planned outcomes were fully reported</td>
</tr>
<tr>
<td>Other bias</td>
<td>Unclear risk</td>
<td>Comment: there is no evidence of additional sources of bias; it is not clear whether the paired data were accounted for in the analysis</td>
</tr>

Oen 2012
### Methods

- **Country where data collected:** Netherlands
- **Parallel-group RCT (multicentre)**
- **Unit of randomisation:** participant
- **Unit of analysis:** participant
- **Duration:** 21 days; follow-up to 12 months

### Participants

- **Inclusion criteria:** adults (aged > 18 years) with acute facial burns (thermal or electrical injuries involving face including scalp, ears and jaw line); neck included only if facial burn extended into it
- **Exclusion criteria:** facial burns < 0.25% TBSA; hospitalised for < 72 h; started with topical treatment before admission; unable to consent
- **Participants:** 154 (179 originally randomised) participants from 3 dedicated burns centres
- **Mean age (years):** 41.9 ± 16.9 vs 41.3 ± 14.5
- **Male participants:** 64 vs 61
- **Burn type:** scald 4 vs 3; flame 70 vs 60; contact 1 vs 2; electrical 2 vs 4; other 1 vs 7
- **Burn degree:** NR
- **Burn size (%TBSA):** median 9.8 (IQR 5.0-19.4) vs 9.3 (4.5-17.0); facial 3.0 (2.0-4.5) vs 3.0 (2.0-4.5)
- **Burn location:** facial

### Interventions

- **Intervention arm 1:** SSD 10 mg/g plus cerium nitrate 22 mg/g (Flammacerium) at admission and once daily for 48-72 h. Wounds were then washed daily with chlorhexidine, rinsed with water and left open. N = 78
- **Intervention arm 2:** SSD 10 mg/g (Flammazine) once daily, covered with plain gauze dressing and a fixation dressing until healed. N = 76
- **Cointerventions:** treatment protocols in clinical practice in Dutch burn centres. Washing with chlorhexidine gluconate (Hibiscrub and rinsing with water)

### Outcomes

- **Primary outcome:** wound healing
- **Secondary outcome:** pain
- **Secondary outcome:** mortality

### Notes

- **Funding:** Dutch Burns Foundation

<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation         | Low risk           | Quote: "To this end, an allocation sequence was developed according to center using mixed randomization (M.N.). Prespecified inequality ranged from two to four, and block sizes varied from four to 11. Randomization sequences were generated with a random numbers table."
Comment: an appropriate method was used to generate the randomisation sequence                                                                                                                                                      |
| (selection bias)                   |                    |                                                                                                                                                                                                                                                                                                                                                         |
| Allocation concealment             | Low risk           | Quote: "The allocation sequence was concealed from the physician enrolling patients, and subversion was prevented by using nontransparent envelopes."
Comment: Does not specifically state sealed envelopes but appears to be appropriate allocation concealment                                                                                                                                                                                    |
| (selection bias)                   |                    |                                                                                                                                                                                                                                                                                                                                                         |
| Blinding of outcome assessment     | High risk          | Quote: "It was not possible to guarantee blinding of the observers to treatment allocation because of the presence and/or involvement in clinical care of most observers. The data analysts (I.O. and M.B.) were blinded."
Comment: stated that assessors could not be guaranteed to be blinded                                                                                                                                                                                                                     |
| (detection bias)                   |                    |                                                                                                                                                                                                                                                                                                                                                         |
| Incomplete outcome data            | Low risk           | Comment: No specific quote but all randomised participants were accounted for in comprehensive flow diagram. There were 25 post-randomisation exclusions for clearly documented reasons mostly related to protocol violations. These were balanced between the groups. 4 deaths occurred (3 vs 1) but these participants were included in the analysis                                                                 |
| (attrition bias)                   |                    |                                                                                                                                                                                                                                                                                                                                                         |
| Selective reporting                | Low risk           | Quote: "Primary outcomes were number of patients requiring surgical intervention and time to complete wound healing......Secondary outcomes consisted of wound colonization, pain, and aesthetic and functional aspects."
Comment: all specified outcomes were fully reported                                                                                                                                                                                                                                          |
| (reporting bias)                   |                    |                                                                                                                                                                                                                                                                                                                                                         |
| Other bias                         | Low risk           | Comment: no specific quote but no other sources of bias identified and good level of reporting                                                                                                                                                                                                                                                           |
## Methods
- Country where data collected: Thailand
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: NR

## Participants
- Inclusion criteria: partial-thickness burn, less than 24 h post-burn injury, TBSA < 15%
- Exclusion criteria: pregnancy, immunocompromised patients and hypersensitivity to treatments used
- Participants: 65
- Mean age (years): 42.31 ± 23.49 vs 31.03 ± 19.76
- Male participants: 15 vs 21
- Burn type: flame 8 (23%) vs 18 (60%)/dcald 27 (77%) vs 10 (33%)/other (chemical, contact burn 0 (0%) vs 2 (7%)
- Burn degree: NR
- Burn size (%TBSA): 2.77 ± 0.41 vs 7.93 ± 1.8
- Burn location: upper limb 31% vs 53%/lower limb 46% vs 33%/hand 11% vs 3%/other 12% vs 11%

## Interventions
- Intervention arm 1: 1% SSD (1% AgSD) covered with dry gauze dressing changed every day until complete wound closure. N = 35
- Intervention arm 2: Alginate silver dressing (Askina Calgitrol Ag) changed every 5 days until complete wound closure. N = 30
- Cointerventions: none reported

## Outcomes
- Primary outcome: wound healing
- Secondary outcome: pain

## Notes
- Funding NR

### Methods

Country where data collected: UK  
Parallel group RCT  
Unit of randomisation: participant  
Unit of analysis: participant  
Duration: NR

### Participants

Inclusion criteria: burns less than 5% TBSA (averaging under 1%) suitable for outpatient treatment  
Exclusion criteria: those needing inpatient treatment, facial burns, hand burns managed in bags and those whose treatment was to be continued elsewhere  
Participants: 196 outpatients  
Mean age (years): < 5 years: 21 vs 24; 5-14 years: 7 vs 9; > 14 years: 64 vs 71  
Male participants: 49 vs 64  
Burn type: NR  
Burn degree: NR  
Burn size (%TBSA): < 1%  
Burn location: NR

### Interventions

Intervention arm 1: hydrocolloid material covered with cotton gauze overlaid with cotton wool and secured with crepe bandage or adhesive tape. Dressing inspected on 3rd or 4th day and then changed weekly unless dressing contaminated or adverse symptoms developed  
Intervention arm 2: chlorhexidine-impregnated tulle-gras dressing covered with cotton gauze overlaid with cotton wool and secured with crepe bandage or adhesive tape. Dressing inspected on 3rd or 4th day and then changed weekly unless dressing contaminated or adverse symptoms developed  
Cointerventions: NR

### Outcomes

Primary outcome: wound healing  
Primary outcome: infection

### Notes

*Piatkowski 2011*
### Methods
- Country where data collected: Netherlands
- Parallel-group RCT
- Unit of randomisation: burns
- Unit of analysis: burns
- Duration: NR

### Participants
- Inclusion criteria: second-degree burns up to 10% TBSA
- Exclusion criteria: Aged > 18 years; dermatological diseases and/or pre-existent polyneuropathy
- Participants: 60 outpatients with 72 burns
- Mean age (years): 46.5 ± 15.6 vs 34 ± 14.2
- Male participants: 19 vs 20
- Burn type: scald 19 vs 19; contact 8 vs 2; flame 5 vs 7
- Burn degree: all second-degree
- Burn size (%TBSA): NR (cm² 151.2 ± 109.6 vs 134.7 ± 99)
- Burn location: hands 2 vs 6; arms 11 vs 13; thorax 2 vs 2; abdomen 4 vs 2; thighs 18 vs 8; feet 1 vs 3

### Interventions
- Intervention arm 1: SSD cream (Flammazine) changed daily. N = 30
- Intervention arm 2: polyhexanide-containing bio-cellulose dressing (Suprasorb X+PHMB) changed every 2nd or 3rd day. N = 30
- Cointerventions:

### Outcomes
- Primary outcome: wound healing
- Secondary outcome: pain
- Secondary outcome: costs

### Notes
- Funding NR
- This was a “split-body” or “intra-individual” design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

| Random sequence generation (selection bias) | Low risk            | Quote: "Suitable patients were assigned to one of the treatment groups, using computer generated randomization."  
Comment: computer-generated randomisation |
| Allocation concealment (selection bias) | Unclear risk        | Quote: "A prospective, randomized, controlled single center study was designed to evaluate clinical efficacy of a polyhexanide containing bio-cellulose dressing (group B) compared to a silver-sulfadiazine cream (group A) in sixty partial-thickness burn patients."  
Comment: no information on whether the allocations to treatment were adequately concealed |
| Blinding of outcome assessment (detection bias) | Low risk            | Quote: "Wound healing was documented using standardized digital photographs, which were assessed by two experienced wound specialists, that were blinded for the treatment."  
Comment: blinded outcome assessment documented although pain assessment probably not blinded |
| Incomplete outcome data (attrition bias) | Low risk            | Comment: no specific quote but all participants accounted for |
| Selective reporting (reporting bias) | Unclear risk        | Comment: no specific quote but although all planned outcomes were reported in some cases the data were only presented graphically |
| Other bias                          | Unclear risk        | Comment: there is potential for unit of analysis issues as they analyse 72 wounds on 60 participants and 2 of the participants had more than one treatment. The data were not useful to our analysis. No other sources of bias were identified and methods were well reported |

Piccolo-Daher 1990
## Methods
- Country where data collected: Brazil
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: burn
- Duration: NR

## Participants
- Inclusion criteria: second-degree burns 1%-20% TBSA
- Exclusion criteria: NR
- Participants: 125
- Mean age (years): NR
- Male participants: NR
- Burn type: NR
- Burn degree: second-degree
- Burn size (%TBSA): mean 4%
- Burn location: NR

## Interventions
- Intervention group 1: merbromin 2% N = 25
- Intervention group 2: sodium salicylate 2% N = 25
- Intervention group: zinc sulfadiazine 2% N = 25
- Intervention group 4: sodium salicylate 2% + zinc sulfadiazine 2% N = 25
- Intervention group 5: collagenase 0.6 μg/g + chloramphenicol 1% N = 25
- Cointerventions: surgical debridement under general anaesthesia; occlusive dressings after topical application

## Outcomes
- Primary outcome: wound healing

## Notes
- Funding NR. Study reported in Portuguese; data extraction and risk of bias provided by two translators. Although the unit of analysis is stated to be "burns" it appears that there was only one burn per participant.

**Radu 2011**
## Methods
- **Country where data collected:** Germany
- **Parallel-group RCT (intra-individual)**
- **Unit of randomisation:** burn
- **Unit of analysis:** burn
- **Duration:** 24 h

## Participants
- **Inclusion criteria:** aged 18-80 years with 2nd-degree partial-thickness burn > 3% TBSA and at least two 10 cm² symmetrical or similar areas for comparison. Abbreviated Burn severity Index score no higher than 10.
- **Exclusion criteria:** NR
- **Participants:** 30 people with burns presenting at burn department of trauma centre
  - **Mean age (years):** median 42
  - **Male participants:** 22/30
  - **Burn type:** scald 12, contact 7, flame 11
  - **Burn degree:** 2nd
  - **Burn size (%TBSA):** median 18 (range 6-36)
  - **Burn location:** trunk 9, thigh 11, lower leg 5, arm 5

## Interventions
- **Intervention arm 1:** SSD (Flammazine); gauze
- **Intervention arm 2:** octenidine gel, gauze
- **Cointerventions:** initial disinfection with Octinisept and removal of blisters; preparation for treatment with synthetic skin substitute

## Outcomes
- **Secondary outcome:** pain

## Notes
- **Funding NR**
- This was a “split-body” or “intra-individual” design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

</table>
**Methods**

- Country where data collected: Pakistan
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 60 days

**Participants**

- Inclusion criteria: partial-thickness burns involving between 5% and 40% TBSA
- Exclusion criteria: NR
- Participants: 50 adults and children with partial-thickness burns
- Mean age (years): range 18 months-50 years
- Male participants: 21/50
- Burn type: NR
- Burn degree: second-degree (partial-thickness)
- Burn size (%TBSA): surface area
- Burn location: NR

**Interventions**

- Intervention arm 1: pure unprocessed, undiluted honey applied once daily, covered with cotton sterilized gauze
- Intervention arms 2: layer of 1% SSD cream applied once daily
- Cointerventions: general management including initial debridement and wound excision were the same in both groups. The wounds were cleansed with normal saline and thorough debridement done.

**Outcomes**

- Primary outcome: wound healing (epithelialisation)
- Primary outcome: infection (culture positive)
- Secondary outcome: pain (VAS 1-10) and time to pain-free status
- Secondary outcome: cost per dressing per %TBSA

**Notes**

- Funding: NR

**Risk of bias table**
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation (selection bias) | Unclear risk       | Quote: "The cases were divided into two groups randomly by consecutive sampling method, in equal numbers."  
Comment: no information on how the randomisation sequence was generated |
| Allocation concealment (selection bias)  | Unclear risk       | Quote: "The cases were divided into two groups randomly by consecutive sampling method, in equal numbers."  
Comment: no information on whether the allocation sequence was adequately concealed |
| Blinding of outcome assessment (detection bias) | Unclear risk       | Quote: "At the time of change of dressing, details regarding the condition of the wound such as signs of infection, condition of the surrounding tissue, discharge, smell, presence of necrotic tissue, and degree of epithelialisation were noted."  
Comment: unclear if this assessment was performed by personnel/assessors blinded to the allocation: since the interventions clearly differ then it may be unlikely that assessment could be blinded if it was performed by those changing the dressings |
| Incomplete outcome data (attrition bias)  | Low risk           | No direct quote but all participants were included in the analysis.                     |
| Selective reporting (reporting bias)      | Unclear risk       | The primary and secondary outcomes were not defined in the methods section so it is difficult to assess if all planned outcomes were reported. |
| Other bias                                | Unclear risk       | No evidence of other sources of bias but reporting insufficient to be certain            |

Silverstein 2011
### Methods
- Country where data collected: USA
- Parallel-group RCT (multicentre)
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 21 days +

### Participants
- Inclusion criteria: aged at least 5 years; had a thermal burn within 36 h of enrolment; 2.5%-20% of TBSA (burns covering between 3% and 25% of TBSA, allowing for up to 10% of TBSA to be third-degree burn); only second-degree burn area treated as per study protocol
- Exclusion criteria: chemical or electrical burn; clinically-infected burn; treatment of the burn with an active agent before study entry, and pregnancy; necrotising leukocytic vasculitis or pyoderma gangrenosa, diagnosed illness (e.g. HIV/AIDS, cancer, severe anaemia); corticosteroid use; other immunosuppressants/chemotherapy in past 30 days; known allergy/hypersensitivity to components; physical/mental condition meaning not expected to comply
- Participants: 101 participants at 10 centres
- Mean age (years) (SE): 37.0 (18.1) vs 39.2 (18.2)
- Male participants: 36/41
- Burn type: scald n=17 vs 9, flash 17 vs 16, flame 13 vs 19, contact 2 vs 4; other 0 vs 3
- Burn degree: second-degree
- Burn size (%TBSA): mean partial-thickness burn size values used within the analysis, 5.64% vs 4.93%.
- Burn location: NR

### Interventions
- Intervention arm 1: silver soft silicone foam (Mepilex Ag). Dressing changes every 5-7 days (3–5 days during the acute phase) depending on the status of the burn. Additional light bandage as needed to ensure fixation
- Intervention arm 2: SSD cream applied once or twice daily to a thickness of approximately 2 mm, then covered with a gauze pad and gauze wrap or other fixation
- Cointerventions: wound cleansing; sharp debridement at baseline

### Outcomes
- Primary outcome: wound healing
- Secondary outcome: adverse events
- Secondary outcome: pain
- Secondary outcome: costs

### Notes
- Funding: Molnlycke Health Care educational grant

*Subrahmanyam 1993b*
### Methods
- Country where data collected: India
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: NR

### Participants
- Inclusion criteria: partial-thickness burns < 40% TBSA
- Exclusion criteria:
  - Participants: 92 people attending a general hospital
  - Mean age (years): 42.8 (3-65)
  - Male participants: 44
  - Burn type: NR
  - Burn degree: NR (partial-thickness)
  - Burn size (%TBSA): 22.7 (15-35) groups 22.8 vs 22.6
  - Burn location: NR

### Interventions
- Intervention arm 1: honey-impregnated gauze prepared by dipping sterile gauze in unprocessed and undiluted honey, covered with pad and bandage, changed on alternate days unless signs of infection
- Intervention arm 2: bio-occlusive, moisture-permeable polyurethane dressing (OpSite) kept in place until day 8 if no sign of infection, leakage etc
- Cointerventions: washed with normal saline

### Outcomes
- Primary outcome: wound healing
- Primary outcome: infection

### Notes
- Funding NR; information on allocation method, allocation concealment, blinding, mean TBSA, mean time to healing and standard deviation for mean time to healing provided by author to Jull et al ([Jull 2015](#))
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors’ judgement</th>
<th>Support for judgement</th>

Subrahmanyam 1994
### Methods
- Country where data collected: India
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: NR

### Participants
- Inclusion criteria: partial-thickness burns less than 40% TBSA within 6 h of burn
- Exclusion criteria: NR
- Participants: 64
  - Mean age (years): 25 vs 24.6 (3-62; 60 aged 21-30)
  - Male participants: 28 vs 15
  - Burn type: scald n = 25 vs 18, flame 12 vs 4, contact burn 3 vs 2
  - Burn degree: NR (partial-thickness)
  - Burn size (%TBSA): 18.5% vs 19.4%
- Burn location: NR

### Interventions
- Intervention arm 1: dry gauze dipped into unprocessed honey and applied to wound, covered with an absorbent dressing that was changed alternate days. Changed more often if signs of infection. N = 40
- Intervention arm 2: amniotic membrane - no other details of dressing given, after day 8 dressing was changed on alternate days, changed more often if signs of infection. N = 24
- Cointerventions: washed with normal saline

### Outcomes
- Primary outcome: wound healing

### Notes
- Funding NR
- Information about allocation method, allocation concealment, blinding, and standard deviation for mean time to healing provided by study author to Jull et al (Jull 2015)

### Methods

Country where data collected: India  
Parallel-group RCT  
Unit of randomisation: participant  
Unit of analysis: participant  
Duration: 21 days

### Participants

Inclusion criteria: less than 40% TBSA burn, hospitalised within 6 h post-burn  
Exclusion criteria:  
Participants: 100 people attending burns unit  
Mean age (years): 26.5 ± 1 vs 25.2 ± 2  
Male participants: 52  
Burn type: NR  
Burn degree: NR  
Burn size (%TBSA): 22.5 ± 3 vs 23.4 ± 1; full-thickness 3.2 +/-2 vs 4.7 +/-1%  
Burn location: NR

### Interventions

Intervention arm 1: 15 mL-30 mL unprocessed honey, dry gauze applied on top and covered with bandage, changed every 2 days. N = 50  
Intervention arm 2: SSD impregnated gauze changed every 2 days. N = 50  
Cointerventions: washed with normal saline

### Outcomes

Primary outcome: wound healing  
Primary outcome: infection (resolution)  
Secondary outcome: resource use (hospital stay)

### Notes

Funding NR  
Information about allocation method, allocation concealment, blinding, and standard deviation for mean time to healing provided by author to Jull et al (*Jull 2015*)

*Tang 2015*
**Methods**

Country where data collected: China  
Parallel-group RCT  
Unit of randomisation: participant  
Unit of analysis: unclear (burn?)  
Duration: 4 weeks

**Participants**

Inclusion criteria: deep partial-thickness thermal burn injury covering 2.5%-25% TBSA (third-degree areas were not to exceed 10% TBSA). aged 5-65 years; at least one isolated burn area not on head or face with deep partial 2nd-degree burn from 1%-10% TBSA  
Exclusion criteria: burns older than 36 h, clinically infected; treated with active agent before study entry (SSD allowed up to 24 h before randomisation); dermatologic disorders or necrotising processes; underlying diseases such as HIV/AIDS, cancer, severe anaemia, insulin-dependent diabetes, systemic glucocorticoid use except occasional prednisolone < 10 mg/d; immunosuppressive agents, radiation or chemotherapy in previous 30 days; known allergy/sensitivity to the products; pregnancy; previous participation in this (or other study within 1 month)  
Participants: 158 randomised participants (total number of burns > 200)  
Mean age (years): 36.2 (range 5.2-65.5; only 5 < 12 years). No difference between groups  
Male participants: 55 vs 57  
Burn type: scald 30 vs 41; flash 8 vs 7; flame 32 vs 31; contact 1 vs 3  
Burn degree & TBSA: 2nd-degree superficial partial 4.48% vs 4.29%; deep partial-thickness 6.28% vs 5.18%; third-degree 0.345% vs 0.317%. enrolled study site: 2.72 vs 2.64  
Burn location: arm 52 vs 53, buttock 6 vs 7, hand 41 vs 42, leg 29 vs 35, thigh 24 vs 31, trunk 26 vs 27, other 43 vs 46

**Interventions**

Intervention arm 1: absorbent foam silver dressing (Mepilex Ag) changed every 5-7 days; gauze wrap as secondary dressing. N = 73  
Intervention arm 2: SSD 1% cream; gauze pad and wrap as secondary dressing. N = 85  
Cointerventions: debrided and/or cleansed according to standard practice

**Outcomes**

Primary outcome: wound healing  
Primary outcome: infection  
Secondary outcome: adverse event  
Secondary outcome: pain

**Notes**

Funding NR

**Risk of bias table**
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation (selection bias)  | Low risk           | Quote: "Enrolled subjects were assigned randomly using a block design, with block sizes varying between 2.4 and 6 (in Viedoc, Pharma Consulting Group, Uppsala, Sweden) to either SSD or Mepilex Ag. Subjects were consecutively allocated to the treatment at each center and given a subject code, depending on which strata they belonged to."  
Comment: randomisation sequence computer-generated using blocking design |
| Allocation concealment (selection bias)      | Low risk           | Quote: "Enrolled subjects were assigned randomly using a block design, with block sizes varying between 2.4 and 6 (in Viedoc, Pharma Consulting Group, Uppsala, Sweden) to either SSD or Mepilex Ag. Subjects were consecutively allocated to the treatment at each center and given a subject code, depending on which strata they belonged to."  
Comment: allocation conducted remotely by consecutive allocation of codes within stratified design |
| Blinding of outcome assessment (detection bias) | Low risk           | Quote: "In addition, the investigator was required to make a subjective assessment of healing at each weekly assessment before cleansing and/or debridement. Percentage of the burn healed since baseline was to be performed by a blinded observer."  
Comment: assessment of healing was conducted by an assessor blinded to the treatment allocation; it's not clear whether assessment of other outcomes was blinded |
| Incomplete outcome data (attrition bias)     | Low risk           | Quote: ".....158 patients were randomized, and 153 patients were subjected to at least one treatment and were included in the ITT population, 71 (46%) of them randomized to Mepilex Ag and 82 (54%) randomized to SSD. Thirteen patients (8%) discontinued before the study ended, 5 (7%) of them from the Mepilex Ag group and 8 (10%) from the SSD group. One patient withdrew consent from the SSD group, while the other 12 discontinued because of other reasons (Fig. 1)."  
Comment: all participants were accounted for and the proportion who discontinued was low and low relative to the event rate for healing |
| Selective reporting (reporting bias)         | Low risk           | Quote: "The primary end point was time to healing (defined as 95% epithelialisation by visual inspection). The secondary end points were percentage of burns epithelialised/healed, numbers of burns healed or not at each visit (not at baseline), number of study burns requiring a skin graft, and number of dressing changes. Additional outcomes were measured assessing the tolerability and performance of the dressings on wound and periwound status, including pain and experience of use of the dressings."  
Comment: the defined outcomes were all fully reported |
| Other bias                                   | Unclear risk       | Comment: it was unclear how the designated burn was chosen in participants with multiple burns. However it was clear that there were no unit of analysis issues.                                                                                                                                                                                                                                  |

Varas 2005
## Methods

- Country where data collected: USA
- Parallel-group RCT (intra-individual)
- Unit of randomisation: burn
- Unit of analysis: burn
- Duration: completion of treatment (max 14 days)

## Participants

- Inclusion criteria: partial-thickness burn injuries requiring topical wound care that, in the opinion of the observer, would not go on to require surgical excision and grafting. The wounds had to involve two areas far enough apart so as not to create interference of the treatments. Wounds of similar sizes were chosen, but not specifically measured.
- Exclusion criteria: NR
- Participants: 14 people attending a hospital/burn centre
- Mean age (years): 41 (25-68)
- Male participants: 13/14
- Burn type: 12 flame, 2 scalding (both arms same cause)
- Burn degree: NR partial-thickness
- Burn size (%TBSA): 14.6% (4.5–27)
- Burn location: upper extremities 8 vs 8, lower extremities 4 vs 6, trunk 2 vs 0

## Interventions

- Intervention arm 1: Acticoat- silver-impregnated membrane applied wet and left in place; moistened and change of overlying dry gauze dressings every 6 h. 14 burns
- Intervention arm 2: SSD - applied and removed then dressed with a dry gauze dressings twice daily. 14 burns
- Cointerventions: NR

## Outcomes

- Primary outcome: wound healing
- Secondary outcome: pain
- Secondary outcome: adverse events

## Notes

- Funding NR
- This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

*Wright 1993*
| Methods | Country where data collected: UK  
Parallel-group RCT  
Unit of randomisation: participant  
Unit of analysis: participant  
Duration: NR |
|---|---|
| Participants | Inclusion criteria: partial-thickness burns manageable through outpatients  
Exclusion criteria: burns requiring grafting, > 48 h post-burn injury, sensitive to dressings, burn on face or hand joints, burn infected, receiving treatment other than first aid or more suited to alternative treatments  
Participants: 98 people presenting at ED/outpatient care. Other characteristics NR but "no statistically significant differences with regard to patient demographics and physical characteristics" (refers to participants included in analysis only) |
| Interventions | Intervention arm 1: hydrocolloid dressing (Granuflex)  
Intervention arm 2: paraffin gauze impregnated with 0.5% chlorhexidine acetate (Bactigras)  
Cointerventions: cleaned with sodium chloride solution and allowed to dry |
| Outcomes | Secondary outcome: pain  
Secondary outcome: resource use |
| Notes | Funded by ConvaTec Ltd |

Risk of bias table
<table>
<thead>
<tr>
<th>Bias</th>
<th>Authors' judgement</th>
<th>Support for judgement</th>
</tr>
</thead>
</table>
| Random sequence generation (selection bias) | Unclear risk       | Quote: "Written, informed consent of the patients was obtained and witnessed, and the patients were randomly allocated to either Granuflex E or Bactigras"  
Comment: no further information on how the randomisation sequence was produced |
| Allocation concealment (selection bias)   | Unclear risk       | Quote: "Written, informed consent of the patients was obtained and witnessed, and the patients were randomly allocated to either Granuflex E or Bactigras"  
Comment: no further information on whether allocation was adequately concealed |
| Blinding of outcome assessment (detection bias) | High risk          | Quote: "At each follow-up attendance the following details were noted: 1. Reason for dressing change. 2. Ease of removal. 3. Wound appearance. 4. Pain while dressing was in situ. 5. Pain on dressing removal or application. 6. Analgesia or antibiotics administered. When the wound had completely healed a final evaluation was made, the quality of healing with regard to re-epithelialization and cosmetic results was noted. The dressing was rated by both the investigator and the patient."  
Comment: it appeared that the investigator was not blinded to treatment allocation and also performed the assessment of outcome |
| Incomplete outcome data (attrition bias)  | High risk          | Quote: "Out of a total of 98 patients involved, 31 patients were withdrawn. Of these, 22 patients were lost to follow-up, two patients requested withdrawal and there was one protocol violation."  
Comment: a large number of participants were lost to follow-up |
| Selective reporting (reporting bias)      | Unclear risk       | Comment: no specific quote but outcomes were not fully prespecified so difficult to determine if all planned outcomes were reported                                                                 |
| Other bias                                | Unclear risk       | Comment: no evidence of other sources of bias but reporting insufficient to be certain                                                                                                                                   |

Yang 2013
**Methods**

- Country where data collected: China
- Parallel-group RCT
- Unit of randomisation: burn
- Unit of analysis: burn
- Duration: 14 days

**Participants**

- Inclusion criteria: total burn < 30% TBSA, deep partial second-degree burn wounds, > one month treatment; residual wound < 10% TBSA, single wound < 5 cm x 5 cm
- Exclusion criteria: no general infection or complications
- Participants: 60 hospital patients each with 2 burns
- Mean age (years): 39 ± 13 (range 18-65)
- Male participants: NR
- Burn type: NR
- Burn degree: NR
- Burn size (%TBSA): NR; size 18 ± 8 cm$^2$ vs 15 ± 10 cm$^2$
- Burn location: NR

**Interventions**

- Intervention arm 1: FLAMIGEL (hydrogel dressing) covered with cotton gauze, changed every day to 7 days, then every other day to 14 days. N = 60 burns
- Intervention arm 2: iodophor gauze covered with cotton gauze, changed every day to 7 days, then every other day to 14 days. N = 60 burns
- Cointerventions:

**Outcomes**

- Primary outcome: wound healing
- Secondary outcome: pain

**Notes**

- Funding NR
- Article in Chinese, extracted and assessed for risk of bias by one review author, discussed with a second review author
- This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

| Other bias                                | Unclear risk       | Reporting insufficient to determine whether the intra-individual design was adjusted for or other risks |

### Yarboro 2013

#### Methods
- Country where data collected: USA
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration:

#### Participants
- Inclusion criteria: superficial partial-thickness burns, 0-4 days post thermal injury < 25% TBSA, aged 11-80 years
- Exclusion criteria: burn on face, ears or scalp; allergic to silver
- Participants: 24 participants attending a wound management centre
- Mean age (years): 33.8 vs 33.9
- Male participants: 18/24
- Burn type: NR
- Burn degree: NR (superficial partial-thickness)
- Burn size (%TBSA): NR (area burned 1103.10 ± 1086.10 cm² vs 753.70 ± 934.30 cm²)
- Burn location: NR

#### Interventions
- Intervention arm 1: Aquacel Ag plus standard care
- Intervention arm 2: SSD plus standard care
- Cointerventions: whirlpool wound cleansing for 15 mins using hexaclorophene + selective debridement followed by wound dressing as per arm and 2nd dressing

#### Outcomes
- Primary outcome: wound healing
- Secondary outcome: pain

#### Notes
- Funding NR

Zahmatkesh 2015
## Methods
- Country where data collected: Iran
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: 20 days

## Participants
- Inclusion criteria: participants with second-degree burns (depth 0.2-5.0 mm) up to 40% TBSA; aged 15-55, referred during first 24 h following injury, negative culture on admission
- Exclusion criteria: participants with underlying conditions such as diabetes, chronic renal or hepatic diseases, and those with simultaneous burns, trauma, and skin lacerations were excluded
- Participants: 30 individuals with superficial or deep partial-thickness burns
- Mean age (years): 24.8 (11.9)
- Male participants: 21/30
- Burn type: direct fire or oil: 26
- Burn degree: partial-thickness burns; deep partial-thickness 6/10 vs 11/20
- Burn size (%TBSA): surface area
- Burn location: NR

## Interventions
- Intervention arm 1: olea ointment which contains 33.4% honey, 33.3% olive oil, and 33.3% sesame oil. After washing the wound with normal saline solution, 3–5 mm thick layer of Olea ointment was applied over the wound and closed dressing was performed every day
- Intervention arms 2: 1.5 mm-thick layer of acetate mafenide ointment (8.5%) every 12 h.
- Cointerventions: debridement as required

## Outcomes
- Primary outcome: wound healing (development of granulation tissue)
- Primary outcome: infection (development of positive culture after 7 days)
- Secondary outcome: adverse events: need for surgical debridement

## Notes
- Funding: Kurdistan University of Medical Sciences

---

Zhou 2011
Methods

- Country where data collected: China
- Parallel-group RCT (intra-individual)
- Unit of randomisation: burn
- Unit of analysis: burn
- Duration: 14 days

Participants

- Inclusion criteria: paediatric superficial second-degree burn wounds within 24 h
- Exclusion criteria: prior treatment; other disease
- Participants: 40 children with burns divided into 2 areas for treatment
- Mean age (years): 4.5 ± 2.2 (2-6)
- Male participants: 22/40
- Burn type: NR
- Burn degree: second-degree
- Burn size (%TBSA): 3.85 ± 1.27 (3-5)
- Burn location: neck or front trunk

Interventions

- Intervention arm 1: Aquacel-Ag, covered by 20 layers gauze; took off the outer layer at Day 3; changed new dressing at Day 7 with debridement
- Intervention arm 2: SD-Ag, covered by 20 layers gauze; took off the outer layer at Day 3; changed new dressing at Day 7 with debridement
- Cointerventions: cleaned the wound with water; 5% chlorhexidine acetate for 2 min then cleaned with water again

Outcomes

- Primary outcome: wound healing

Notes

- Funding NR
- Article in Chinese, extracted and assessed for risk of bias by one review author, discussed with a second review author
- This was a "split-body" or "intra-individual" design where a person with two wounds had one wound randomised to each treatment. It was not clear whether the analysis took account of this.

Footnotes

RCT: randomised controlled trial; SSD: silver sulfadiazine

Characteristics of studies awaiting classification

Gao 2016
### Methods
- Country where data collected: NR
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: unclear

### Participants
- Inclusion criteria: irrespective of age with deep-dermal burn wound; admitted to hospital less than 3 days after burn; the burn wounds were not to be operated on
- Exclusion criteria: burn wound involved the head and face region; history of allergy to dressing composed of ionic silver; serious infective wound; required emergency surgery
- Participants: 10 individuals; no details of participant characteristics were reported

### Interventions
- Intervention arm 1: silver-impregnated antimicrobial dressing combined with a granulocyte macrophage colony-stimulating factor (GM-CSF) gel
- Intervention arms 2: gauze dressing combined with GM-CSF gel
- Cointerventions: the GM-CSF gel was applied in both arms

### Outcomes
- Primary outcome: no primary outcomes were reported
- Secondary outcome: pain
- Secondary outcome: resource use - time to debridement complete; no outcomes currently have evaluable data

### Notes
- Funding: NR
- Reported as abstract only; study author contact not yet established
- Appears to be assessing time to debridement rather than the outcomes of this review

### Liu 2016
- Country where data collected: China
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: participant
- Duration: NR

### Participants
- Inclusion criteria: participants with deep partial-thickness burn wounds
- Exclusion criteria: NR
- Participants: 366 participants

### Interventions
- Intervention arm 1: gauze with iodophor
- Intervention arms 2: recombinant human granulocyte-macrophage colony-stimulating factor (rhGM-CSF) gel
- Cointerventions: NR

### Outcomes
- Primary outcome: complete wound healing time
- Secondary outcome: adverse events

### Notes
- Paper in Chinese. Awaiting obtaining full text and translator assessment; details here based on English abstract
### Santi 2013

**Methods**
- Country where data collected: NR
- Parallel-group RCT
- Unit of randomisation: unclear
- Unit of analysis: unclear
- Duration: unclear

**Participants**
- Inclusion criteria: children with second-degree burns
- Exclusion criteria: NR
- Participants: 27 children in the intervention group, control group
- Mean age (years): 5 (range 4 months-14 years)
- Male participants: 16
- Burn type: NR
- Burn degree: second
- Burn size (%TBSA): NR
- Burn location: NR

**Interventions**
- Intervention arm 1: alginate with embedded anti-bacterial enzyme system
- Intervention arm 2: NR
- Cointerventions: NR

**Outcomes**
- Primary outcome: wound healing
- Primary outcome: infection
- Secondary outcome: pain
- Secondary outcome: adverse events(?)

**Notes**
- Reported in abstract form only, very limited information

---

### Wang 2015

**Methods**
- Country where data collected: India
- Parallel-group RCT
- Unit of randomisation: participant
- Unit of analysis: unclear
- Duration: at least 2 weeks

**Participants**
- Patients with burns (N = 17)

**Interventions**
- Azadirachta indica (formulation unclear)
- SSD (formulation unclear)

**Outcomes**
- Wound area? (ulcer score)
- Healing? (healing without deformity)
- Adverse events? (scar-related events reported)

**Notes**
- Abstract assessed; full text unobtainable
### Methods
- Country where data collected: China
- Intra-individual RCT
- Unit of randomisation: burn area
- Unit of analysis: burn area
- Duration: NR

### Participants
- Inclusion criteria: participants with deep or superficial partial-thickness facial burn wounds
- Exclusion criteria: NR
- Participants: 25 participants, 10 with deep partial-thickness and 15 with superficial partial-thickness facial burns

### Interventions
- Intervention arm 1: silver hydrocolloid
- Intervention arms 2: biological dressing (porcine xenoderm [sic])
- Cointerventions: NR

### Outcomes
- Primary outcome: wound healing time
- Primary outcome: infection
- Secondary outcome: resource use, possibly also pain

### Notes
- Paper in Chinese. Awaiting obtaining full text and translator assessment; details here based on English abstract

---

**Footnotes**
- NR: not reported; RCT: randomised controlled trial; SSD: silver sulfadiazine

**Characteristics of ongoing studies**

**Summary of findings tables**

*The risk in the intervention group (and its 95% confidence interval) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).

CI: confidence interval; HR: hazard ratio; MD: mean difference; RR: risk ratio; SSD: silver sulfadiazine

GRADE Working Group grades of evidence

High: it is very likely that the effect will be close to what was found in the research.

Moderate: it is likely that the effect will be close to what was found in the research, but there is a possibility that it will be substantially different.

Low: it is likely that the effect will be substantially different from what was found in the research, but the research provides an indication of what might be expected.

Very low: the anticipated effect is very uncertain and the research does not provide a reliable indication of what might be expected.

Footnotes

¹Not downgraded for risk of selection bias and detection bias because most participants were in a study at low risk of bias; downgraded twice for serious imprecision due to low numbers of participants and wide confidence intervals.

²Downgraded once for high risks of bias across varying domains (variously detection, selection, reporting and other sources
of bias in 5 trials representing 31% of the analysis weight); downgraded once for inconsistency ($I^2 = 78\%$). A post-hoc sensitivity analysis excluding studies with unit of analysis issues or intra-individual designs did not materially affect result.

4Downgraded once due to risk of detection bias affecting 51% of the analysis weight across 3 of 4 studies; downgraded once for indirectness from largest trial outcome (49% analysis weight), which related to inflammation and once due to imprecision.

5Downgraded once for high risks of detection bias affecting 93% of analysis weight; downgraded once for indirectness. Studies with intra-individual design or unit of analysis issue contributed no weight to analysis due to zero events.

### 2 Honey versus topical antibiotics

#### Patient or population: people with burns

**Intervention:** honey  
**Comparison:** topical antibiotics (SSD or mafenide acetate)

**Setting:** hospitals and burn clinics

<table>

</tr>
</tbody>
</table>

Footnotes

1 Downgraded once for imprecision. A post-hoc sensitivity analysis excluding a study with an intra-individual design made no material difference to the analysis.
2 Downgraded twice for imprecision and once for inconsistency; the downgrading for imprecision is based on the post-hoc sensitivity analysis excluding a trial with an intra-individual design. This is a conservative approach to the inclusion of this data. The result of the sensitivity analysis was to produce confidence intervals which included the possibility of both harm and benefit (MD -4.36; 95% CI -8.90 to 0.16).
3 Downgraded once for imprecision and once for inconsistency.
4 Downgraded twice for indirectness as the relationship between the surrogate outcome of positive swabs and clinical infection (used in all except one trial) is unclear, and once for imprecision due to low numbers of events.
5 Downgraded once because of risks of detection bias in the trial which contributes all the weight in the analysis, and twice because of imprecision.

**Moderate:** it is likely that the effect will be close to what was found in the research, but there is a possibility that it will be substantially different.

**Low:** it is likely that the effect will be substantially different from what was found in the research, but the research provides an indication of what might be expected.

**Very low:** the anticipated effect is very uncertain and the research does not provide a reliable indication of what might be expected.

---

4 Iodine versus topical antibiotics

---

**Footnotes**

¹ Downgraded twice for very serious imprecision.

² Downgraded once for risk of detection bias in a trial accounting for 47% of the analysis weight; once for inconsistency ($I^2 = 94$%) and twice for imprecision. A post-hoc sensitivity analysis excluding the trial with the intra-individual design did not materially affect the result of the analysis.

³ Downgraded once for risk of detection bias in a trial accounting for 84% of the analysis weight, and twice for imprecision. A post-hoc sensitivity analysis excluding the trial with the intra-individual design did not materially affect the result of the analysis.

**GRADE Working Group grades of evidence**

- **High:** it is very likely that the effect will be close to what was found in the research.
- **Moderate:** it is likely that the effect will be close to what was found in the research, but there is a possibility that it will be substantially different.
- **Low:** it is likely that the effect will be substantially different from what was found in the research, but the research provides an indication of what might be expected.
- **Very low:** the anticipated effect is very uncertain and the research does not provide a reliable indication of what might be expected.

---

**Footnotes**

\textsuperscript{1}Downgraded once for detection bias in one trial accounting for 61% of the analysis weight and twice for imprecision due to low participant numbers and confidence intervals that cross the line of no effect; one study also had an intra-individual design, which may not have been accounted for in the analysis, this is taken account of in the double downgrading for imprecision.

\textsuperscript{2}Downgraded once for detection bias in the single trial and twice for imprecision due to fragile confidence intervals, which cross the line of no effect.

5 Silver versus non-antibacterial

Footnotes

1. Downgraded twice for imprecision due to wide confidence intervals, which cross the line of no effect, and fragility due to small numbers of participants.
2. Downgraded twice for imprecision due to wide confidence intervals, which cross the line of no effect, and fragility due to small numbers of participants. The study with unit of analysis issues did not contribute to the analysis.
3. Downgraded once due to risk of detection bias and once due to attrition bias in a trial with 90% of the analysis weight and twice due to imprecision.
4. Downgraded once due to risk of detection bias and once due to attrition bias in the single trial; downgraded once for imprecision as confidence intervals cross line of no effect.

8 Iodine versus non-antibacterial
Iodine-based treatments versus non-antibacterial treatments (dressings and topical treatments)

**Patient or population:** people with burns

**Intervention:** iodine-based treatments

**Comparison:** non-antibacterial treatments (dressings and topical treatments)

**Setting:** hospitals and burn clinics

<table>
<thead>
<tr>
<th>Outcomes</th>
<th>Anticipated absolute effects* (95% CI)</th>
<th>Relative effect (95% CI)</th>
<th>Nº of participants (studies)</th>
<th>Certainty of the evidence (GRADE)</th>
<th>Comments</th>
</tr>
</thead>
</table>
| Wound healing (number of healing events): iodophor versus hydrogel | Risk with non-antibacterial treatments: 700 per 1000 | Risk with iodine-based treatments: 119 per 1000 (56 to 238) | RR 0.17 (0.08 to 0.34) | 120 (1 RCT) | ⊗⊗⊗⊗ Low¹ | There may be a smaller number of healing events at 26 days in participants treated with iodophor compared with those treated with hydrogel.

**Risk difference:** 581 fewer wounds healed per 1000 at 14 days with iodophor treatment compared with hydrogel (644 fewer to 462 fewer)

**Wound healing (mean time to healing): iodine gauze versus carbon fibre**

| The mean time to wound healing - iodine gauze versus carbon fibre was 15.29 days | The mean time to wound healing - iodine gauze versus carbon fibre in the intervention group was 5.38 days longer (3.09 longer to 7.67 longer) | MD 5.38 (3.09 to 7.67) | 277 (1 RCT) | ⊗⊗⊗⊗ Very low² | The clinical heterogeneity between these studies, both in terms of interventions and comparators, combined with the wide divergence in effects meant that they could not meaningfully be pooled. It is very uncertain what the effect of iodine compared with non-antibacterial dressings/topical treatments is on mean time to wound healing.

**Risk difference:** 106 fewer days per 1000 participants treated with iodine gauze compared with hydrogel (74 fewer to 238 fewer)

**Infection: iodine gauze versus MEBO**

| The mean time to wound healing - iodophor versus MEBO was 57 days | The mean time to wound healing - iodophor versus MEBO in the intervention group was 26 days shorter (30.48 shorter to 21.52 shorter) | MD -26.00 (-30.48 to -21.52) | 55 (1 RCT) | ⊗⊗⊗⊗ Low³ | There may be little or no difference in the incidence of infection in participants treated with iodine gauze compared with those treated with MEBO.

**Risk difference:** 58 per 1000 per 1000 with iodine gauze compared with MEBO (31 fewer to 151 more)

**Adverse effects: iodine gauze versus MEBO**

| The mean time to wound healing - iodophor versus MEBO was 57 days | The mean time to wound healing - iodophor versus MEBO in the intervention group was 26 days shorter (30.48 shorter to 21.52 shorter) | MD -26.00 (-30.48 to -21.52) | 55 (1 RCT) | ⊗⊗⊗⊗ Low³ | There may be little or no difference in the incidence of adverse effects in participants treated with iodine gauze compared with those treated with MEBO.

**Risk difference:** 106 fewer days per 1000 participants treated with iodine gauze compared with hydrogel (74 fewer to 238 fewer)

**Risk difference:** 31 fewer participants with adverse events with iodine gauze compared with MEBO (74 fewer to 73 more)

**Risk difference:** 106 fewer days per 1000 participants treated with iodine gauze compared with hydrogel (74 fewer to 238 fewer)

**Risk difference:** 31 fewer participants with adverse events with iodine gauze compared with MEBO (74 fewer to 73 more)

---

*The risk in the intervention group (and its 95% confidence interval) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).

**CI:** confidence interval; **MD:** mean difference; **MEBO:** moist exposed burn ointment; **RR:** risk ratio

**GRADE Working Group grades of evidence**

**High:** it is very likely that the effect will be close to what was found in the research.

**Moderate:** it is likely that the effect will be close to what was found in the research, but there is a possibility that it will be substantially different.

**Low:** it is likely that the effect will be substantially different from what was found in the research, but the research provides an indication of what might be expected.

**Very low:** the anticipated effect is very uncertain and the research does not provide a reliable indication of what might be expected.

---

*Footnotes*
Downgraded twice for imprecision due to wide confidence intervals and fragility due to small numbers of participants and uncertainty about the analysis of an intra-individual design.

Downgraded twice for inconsistency and once for imprecision; there were different directions of effect in the two trials, which it is unclear can be reliably attributed to differences between the treatments although these were present; small numbers of participants in each trial also resulted in imprecision for individual estimates.

Downgraded twice for imprecision due to wide confidence intervals, which include the possibility of both benefit and harm for the intervention.

Footnotes
CN: cerium nitrate; MEBO: moist exposed burn ointment; NR: not reported; NS: not significant; SD: standard deviation; SSD: silver sulfadiazine

*a* Chen 2006 assessed the following relevant comparisons between antiseptic (silver) and non-antibacterial (Vaseline gauze) and between silver and SSD

*b* Li 1994 assessed the following relevant comparisons between two antiseptics (ethacridine lactate and iodophor), between ethacridine lactate and a non-antibacterial treatment (MEBO) and between iodophor and MEBO.

*c* Thomas 1995 the following relevant comparisons between antiseptic (chlorhexidine) and topical antibiotic (silver sulfadiazine) and between chlorhexidine and a non-antibacterial treatment (hydrocolloid)

*d* Piccolo-Daher 1990 assessed the following relevant comparisons: Merbromin vs sodium salicylate and Merbromin vs zinc sulfadiazine; other comparisons were not relevant to the review

**Footnotes**

CN: cerium nitrate; MEBO: moist exposed burn ointment; NR: not reported; SSD: silver sulfadiazine

*a* Chen 2006 also assessed a relevant comparison between antiseptic (silver) and non-antibacterial (Vaseline gauze)

*b* Li 1994 also assessed relevant comparisons between two antiseptics (ethacridine lactate and iodophor), between ethacridine lactate and a non-antibacterial treatment (MEBO) and between iodophor and MEBO.

*c* Thomas 1995 also assessed a relevant comparison between antiseptic (chlorhexidine) and topical antibiotic (silver sulfadiazine).

*d* Piccolo-Daher 1990 also assessed a relevant comparison between an antiseptic and topical antibiotic (zinc sulfadiazine).

### Footnotes

- C-E: cost-effectiveness; CN: cerium nitrate; ICER: incremental cost-effectiveness ratio; MEBO: moist exposed burn ointment; NR: not reported; NS: not significant; SD: standard deviation; SEM: standard error of mean; SSD: silver sulfadiazine; TBSA: total body surface area; VAS: visual analogue scale
- **Chen 2006** also assessed a relevant comparison between antiseptic (silver) and non-antibacterial (Vaseline gauze)
- **Li 1994** also assessed relevant comparisons between two antiseptics (ethacridine lactate and iodophor), between ethacridine lactate and a non-antibacterial treatment (MEBO) and between iodophor and MEBO.
- **Thomas 1995** also assessed a relevant comparison between antiseptic (chlorhexidine) and topical antibiotic (silver sulfadiazine).
- **Piccolo-Daher 1990** also assessed a relevant comparison between an antiseptic and topical antibiotic (zinc sulfadiazine).

2 Assessment of risk of bias

The Cochrane tool for assessing risk of bias

1. Was the allocation sequence randomly generated?

Low risk of bias
The investigators describe a random component in the sequence generation process such as: referring to a random number table; using a computer random-number generator; coin tossing; shuffling cards or envelopes; throwing dice; drawing of lots.

**High risk of bias**

The investigators describe a non-random component in the sequence generation process. Usually, the description would involve some systematic, non-random approach, for example: sequence generated by odd or even date of birth; sequence generated by some rule based on date (or day) of admission; sequence generated by some rule based on hospital or clinic record number.

**Unclear**

Insufficient information about the sequence generation process provided to permit a judgement of low or high risk of bias.

2. Was the treatment allocation adequately concealed?

**Low risk of bias**

Participants and investigators enrolling participants could not foresee assignment because one of the following, or an equivalent method, was used to conceal allocation: central allocation (including telephone, web-based and pharmacy-controlled randomisation); sequentially-numbered drug containers of identical appearance; sequentially-numbered, opaque, sealed envelopes.

**High risk of bias**

Participants or investigators enrolling participants could possibly foresee assignments and thus introduce selection bias, such as allocation based on: use of an open random allocation schedule (e.g. a list of random numbers); assignment envelopes without appropriate safeguards (e.g. envelopes were unsealed, non-opaque, or not sequentially numbered); alternation or rotation; date of birth; case record number; any other explicitly unconcealed procedure.

**Unclear**

Insufficient information provided to permit a judgement of low or high risk of bias. This is usually the case if the method of concealment is not described, or not described in sufficient detail to allow a definite judgement, for example if the use of assignment envelopes is described, but it remains unclear whether envelopes were sequentially numbered, opaque and sealed.

3. Blinding - was knowledge of the allocated interventions adequately prevented during the study?

**Low risk of bias**

Any one of the following.
- No blinding, but the review authors judge that the outcome and the outcome measurement are not likely to be influenced by lack of blinding.
- Blinding of participants and key study personnel ensured, and unlikely that the blinding could have been broken.
- Either participants or some key study personnel were not blinded, but outcome assessment was blinded and the non-blinding of others unlikely to introduce bias.

**High risk of bias**

Any one of the following.
- No blinding or incomplete blinding, and the outcome or outcome measurement is likely to be influenced by lack of blinding.
- Blinding of key study participants and personnel attempted, but likely that the blinding could have been broken.
- Either participants or some key study personnel were not blinded, and the non-blinding of others likely to introduce bias.

**Unclear**

Either of the following.
- Insufficient information to permit judgement of low or high risk of bias.
- The study did not address this outcome.

4. Were incomplete outcome data adequately addressed?

**Low risk of bias**

Any one of the following.
- No missing outcome data.
- Reasons for missing outcome data are unlikely to be related to true outcome (for survival data, censoring unlikely to be introducing bias).
- Missing outcome data are balanced in numbers across intervention groups, with similar reasons for missing data across groups.
- For dichotomous outcome data, the proportion of missing outcomes compared with the observed event risk is not enough to have a clinically relevant impact on the intervention effect estimate.
- For continuous outcome data, a plausible effect size (difference in means or standardised difference in means) among missing outcomes is not enough to have a clinically relevant impact on the observed effect size.
- Missing data have been imputed using appropriate methods.

**High risk of bias**
Any one of the following.

- Reasons for missing outcome data are likely to be related to the true outcome, with either an imbalance in numbers or reasons for missing data across intervention groups.
- For dichotomous outcome data, the proportion of missing outcomes compared with the observed event risk is enough to induce clinically relevant bias in the intervention effect estimate.
- For continuous outcome data, a plausible effect size (difference in means or standardised difference in means) among missing outcomes is enough to induce a clinically relevant bias in the observed effect size.
- ‘As-treated’ analysis done with a substantial departure of the intervention received from that assigned at randomisation.
- Potentially inappropriate application of simple imputation.

Unclear

Either of the following.

- Insufficient reporting of attrition/exclusions to permit a judgement of low or high risk of bias (e.g. number randomised not stated, no reasons for missing data provided).
- The study did not address this outcome.

5. Are reports of the study free of suggestion of selective outcome reporting?

Low risk of bias

Either of the following.

- The study protocol is available and all of the study’s prespecified (primary and secondary) outcomes that are of interest in the review have been reported in the prespecified way.
- The study protocol is not available but it is clear that the published reports include all expected outcomes, including those that were prespecified (convincing text of this nature may be uncommon).

High risk of bias

Any one of the following.

- Not all of the study’s prespecified primary outcomes have been reported.
- One or more primary outcomes is/are reported using measurements, analysis methods, or subsets of the data (e.g. subscales) that were not prespecified.
- One or more reported primary outcomes was/were not prespecified (unless clear justification for their reporting is provided, such as an unexpected adverse effect).
- One or more outcomes of interest in the review is/are reported incompletely so that they cannot be entered in a meta-analysis.
- The study report fails to include results for a key outcome that would be expected to have been reported for such a study.

Unclear

Insufficient information provided to permit a judgement of low or high risk of bias. It is likely that the majority of studies will fall into this category.

6. Other sources of potential bias

Low risk of bias

The study appears to be free of other sources of bias.

High risk of bias

There is at least one important risk of bias. For example, the study:

- had a potential source of bias related to the specific study design used; or
- has been claimed to have been fraudulent; or
- had some other problem.

Unclear

There may be a risk of bias, but there is either:

- insufficient information to assess whether an important risk of bias exists; or
- insufficient rationale or evidence that an identified problem will introduce bias.

3 Risk of bias in cluster-randomised trials

In cluster-randomised trials, particular biases to consider include:

- recruitment bias;
- baseline imbalance;
- loss of clusters;
- incorrect analysis; and
- comparability with individually-randomised trials.

**Recruitment bias**: can occur when individuals are recruited to the trial after the clusters have been randomised, as the knowledge of whether each cluster is an ‘intervention’ or ‘control’ cluster could affect the types of participants recruited.
Baseline imbalance: cluster-randomised trials often randomise all clusters at once, so lack of concealment of an allocation sequence should not usually be an issue. However, because small numbers of clusters are randomised, there is a possibility of chance baseline imbalance between the randomised groups, in terms of either the clusters or the individuals. Although this is not a form of bias as such, the risk of baseline differences can be reduced by using stratified or pair-matched randomisation of clusters. Reporting of the baseline comparability of clusters, or statistical adjustment for baseline characteristics, can help reduce concern about the effects of baseline imbalance.

Loss of clusters: occasionally complete clusters are lost from a trial, and have to be omitted from the analysis. Just as for missing outcome data in individually-randomised trials, this may lead to bias. In addition, missing outcomes for individuals within clusters may also lead to a risk of bias in cluster-randomised trials.

Incorrect analysis: many cluster-randomised trials are analysed by incorrect statistical methods that do not take the clustering into account. Such analyses create a ‘unit of analysis error’ and produce over-precise results (the standard error of the estimated intervention effect is too small) and P values that are too small. They do not lead to biased estimates of effect. However, if they remain uncorrected, they will receive too much weight in a meta-analysis.

Comparability with individually-randomised trials: in a meta-analysis that includes both cluster-randomised and individually-randomised trials, or includes cluster-randomised trials with different types of clusters, possible differences between the intervention effects being estimated need to be considered. For example, in a vaccine trial of infectious diseases, a vaccine applied to all individuals in a community would be expected to be more effective than a vaccine applied to only half the people. Another example is provided by discussion of a Cochrane Review of hip protectors (Hahn 2005), where cluster trials showed a large positive effect, whereas individually-randomised trials did not show any clear benefit. One possibility is that there was a ‘herd effect’ in the cluster-randomised trials (which were often performed in nursing homes, where compliance with using the protectors may have been enhanced). In general, such ‘contamination’ would lead to underestimates of effect. Thus, if an intervention effect is still demonstrated despite contamination in those trials that were not cluster-randomised, a confident conclusion about the presence of an effect can be drawn. However, the size of the effect is likely to be underestimated. Contamination and ‘herd effects’ may be different for different types of cluster.
