ABSTRACT: In this work, a comprehensive series of experiments is conducted to investigate the drying behavior of micro- and nanosized particle dispersions. To this end, an acoustic levitator was used to study the drying kinetics of single droplets. The temporal evolution of the actual droplets was recorded using a complementary metal oxide semiconductor (CMOS) camera, and the solid grains produced at the end of drying were investigated by scanning electron microscopy (SEM) imaging. At the end of drying, the grains show different morphologies as a function of the particle size, concentration, and initial droplet volume. We combine these experimental data to show the drying behavior is dependent on all the parameters and that the data all collapse when plotted against the Péclet number. This resulted in a novel characteristic diagram which allows one to predict the shape of the dried colloidal droplet based on Pe. Our results extend the fundamental understanding of the mechanisms controlling the drying of droplet suspensions.

1. INTRODUCTION

The interest and use of colloidal silica as a precursor in various industrial processes are due to its many advantageous properties including low toxicity, chemical stability, and high colloidal stability in various conditions.1-3 It is used widely in applications such as postsynthesis surface modification,4,5 drug carriers,6,7 catalytic supports,8,9 and antifouling coatings10,11 and has factored significantly in nanoparticle research and particle formation from the drying of suspensions.12-14 Understanding the drying of droplet suspensions is of great importance to a variety of processes such as production of catalyst, ceramic, and various pharmaceutical products.15-17 Many of these products, such as paint pigments and milk powders, are manufactured in a complex industrial process typically through spray drying, whereby spray generation followed by solvent evaporation leads to the assembly of dried grains with different characteristics. To improve the efficiency of spray drying and control the morphology of the resulting final grains, it is crucial to develop understanding of the mechanisms governing the drying of droplets. The need to achieve such a more complete knowledge is motivating the scientific community to investigate this process.18

The drying kinetics of droplets containing suspended particles might be divided into two stages,19 illustrated schematically in Figure 1. During stage-1 drying, the so-called constant rate period, solvent evaporation from the surface results in a constant shrinkage of its size. The volume change over time during this period resembles that of a pure droplet (i.e., in the absence of suspended particles). Stage-2 drying, the so-called falling rate period, begins at the critical moisture content, Xcr, when the solvent from the interior of the droplet can no longer keep the entire surface saturated and a shell is formed as a result of particle deposition at the liquid—air interface. Evaporation continues in this stage through the pores of the shell, until the equilibrium moisture content, Xeq, is reached. At this point the resulting particles are typically both dry and rigid.

The morphology and surface properties of dried particles emerging from the drying of suspensions are strongly influenced by the general dynamics of the drying process, the properties of the suspension, and the operating conditions.20-25 Lin and Gentry20 conducted a comprehensive series of experiments to investigate spray drying drop morphology. They concluded that the dried grain morphology was the result of an interplay between several physicochemical parameters, such as operating conditions (e.g., temperature), initial particle concentration, and material properties. Sen et al.21 investigated

the effect of the concentration of suspended particles on the morphological transition in spray drying. In particular, they showed that low particle concentrations led to the creation of a doughnut-like grain as a result of droplet drying. By contrast, because of the reduction of deformation during drying, the same authors showed that increasing particle concentration resulted in the formation of spherical grains. Tsapis et al.26 illustrated the importance of competition between diffusion and convection during the formation of large porous grains formed as a result of drying of suspensions. Similarly, Trueman et al.27,28 proposed a model balancing particulate diffusion with the evaporation rate in the drying of films. It was shown that with careful control of the drying dynamics, the presence of different sized particles can be used to manipulate the film morphology resulting in stratification. Baldwin et al.29 investigated the drying of sessile droplets of aqueous poly-(ethylene oxide) (PEO) polymer solutions. Droplets either form a disk-like solid puddle or a tall conical pillar. The final shape of the deposit is shown to depend on many experimentally controllable parameters.

Single droplet drying techniques have been widely used to investigate the drying of solid–liquid droplets as the resulting morphologies have generally been shown to be similar to those produced by industrial spray drying. There are several methods used to investigate the drying of single droplets, some of which involve suspending a droplet from a thin filament or free falling of a droplet through a tall tower. Early work by Ranz and Marshall13,34 investigated the rate of evaporation and water drops containing dissolved solid particles. Similarly, Baldwin et al.29 proposed a model to describe the formation of internal bubbles during air drying of a droplet containing dissolved solid. They assumed that once the equilibrium vapor pressure of the moisture inside the droplet exceeds the pressure of the ambient air, the grain inflates instantaneously and ruptures into solid hollow spheres playing a significant role in the morphology of final grains.

Using an acoustic levitator to investigate the physics of droplet drying with the associated morphology of the resulting final grain offers several advantages compared to other conventional methods, especially, the absence of mechanical contact with the droplet. Kastner et al.31 experimentally determined the evaporation rates of drops containing water and glass beads by using an acoustic levitator. Both stages of drying were quantified by estimating the droplet volume and measuring the vertical location of the droplet with a CCD camera. Keita et al.41 recently reported the presence of soft polymer particles suspended in granular packings lead to a significant decrease in the drying rate which was related to the bulk fluid properties.

Despite the recent advances toward a complete understanding of the drying of suspension, there is still a need to contribute to the fundamental aspects of the mechanism that determines the shape of the final grain resulting from the drying of a droplet suspension. Although several groups have investigated the effects of primary particle size on the morphology of the final grains, the complex dynamics of particle deposition and interaction with the evaporating solvent (eventually shaping the morphology of the final particle) are not fully understood yet. Motivated by the relevant impact of the drying of suspensions on key industrial applications, we investigate, from a physical perspective, how wide ranges of size and concentration of suspended particles influence the drying dynamics and the shape and morphology of the final dried grains. We then combine these experimental data into a dimensionless Pe number to show that the drying behavior is dependent on all the parameters and that the data all collapse when plotted against $Pe$, thus resulting in the development of a characteristic diagram relating the shape of the final grain to the dimensionless Pélet number.

### 2. THEORETICAL METHODS

During drying, the suspended particles are transported to the interface between air and water via convective transport where the liquid evaporation occurs. This results in preferential particle deposition at the interface. Simultaneously, diffusive

**Figure 2.** Conceptual picture schematically illustrating the drying of droplets containing nanosized particles (a−d) and micrometer-sized particles (e−h) leading to the final dried grain.
transport tends to homogenize the particle concentration over space. This is similar to what occurs during drying of granular materials saturated with salty water or in solidification of suspensions. Therefore, the final particle morphology is influenced by the competition between diffusion and convection, which is normally quantified by the dimensionless Péclet number \( (Pe) \). The Péclet number for the drying of droplets containing suspended particles can be defined as \( (Tsapis \ et \ al.^{26}) \)

\[
Pe = \frac{R^2}{D \cdot t_{dry}}
\]

where \( R \) is the radius of droplet, \( t_{dry} \) the drying time, and \( D \) the collective diffusion coefficient of the suspended particles. For spherical particles, \( D \) can be calculated by using the Stokes–Einstein equation:

\[
D = \frac{k_B T}{6 \pi \eta r}
\]

where \( k_B \) is the Boltzmann’s constant, \( \eta \) the viscosity of the solvent, \( T \) the absolute temperature, and \( r \) the radius of the suspended particles. Note that, for charged particles, such as those used here, \( D \) can be enhanced by the interparticle interactions by a factor of 10.\(^{37,48} \)

At low \( Pe \), the diffusive transport is comparable to the convective transport (or may be even the dominating transport mechanism at \( Pe \ll 1 \)). Therefore, the particle concentration tends to be uniform throughout the entire droplet. In such cases, as evaporation proceeds, the droplet shrinks and the spherical grain forms at the end of the drying process illustrated schematically in Figure 2 (a–d). By contrast, when \( Pe \) is sufficiently high, convective transport dominates over the diffusive transport. In this case, as evaporation proceeds, this results in a preferential particle accumulation at the evaporation front (i.e., the interface between air and liquid).

As the liquid–vapor interface recedes, packing of solutes leads to the formation of a permeable rigid skin formed at the drop surface. Capillary forces will draw particles together, and ultimately van der Waals forces can lock them in place \( (Tsapis \ et \ al.^{26}) \). Particle accumulation at the front leads to thickening of the skin eventually converting the evaporation front to a porous and rigid crust, which encloses the remaining fluid. The subsequent evaporation will continue via flow and evaporation through the crust. Because of the effects of particle settling, the crust formed at the top of the grain is thinner and therefore more susceptible to deformation, compared to the lower region. Such a mechanism may lead to the formation of hollow grains. As the droplet shrinks, the stress generated by the receding vapor–liquid interface may cause breakage in the region where the cohesion of the shell is weaker. The inward collapse at the surface leads to the formation of a half apricot-shape, as shown in Figure 2e–h. Indeed, the crust formation in the drying of suspension droplets can be influenced by the size and concentrations of the suspended particles,\(^ {49} \) and the origin of the breakage lies in the inhomogeneity of the shell, which is similar to what has been observed in the drying of latex suspension droplets deposited on a surface.\(^ {50} \)

To validate the above mechanism, we have conducted a comprehensive series of experiments to investigate the effects of \( Pe \) on the shape and morphology of grains formed at the end of drying of suspensions. The results of these experiments, which provide the scientific justification to the observations synthesized in Figure 2, are described in the following section.

3. EXPERIMENTAL METHODS
An ultrasonic acoustic levitator (tecS AG, U.K.) with a standard operating frequency of 58 kHz was used to investigate the drying of suspended droplets and the morphology of the final grains formed at the end of drying. The levitator consists of a reflector, a concave piezoelectric transducer, and a micrometer screw to adjust the vertical positioning. A standing wave is generated between the transducer and reflector, in which a single drop can be inserted and suspended in a stationary position. Droplets with diameters in the range of \( 0.2–2.5 \) mm can be levitated below the pressure nodes as a result of axial radiation pressure and radial Bernoulli stress.\(^ {51} \)

All of the droplet experiments were performed using deionized water in ambient conditions. Colloidal silica is used here as the main precursor because of its well-known and established chemistry and its relevance in industrial applications.\(^ {13} \) To cover a wide range of values, we investigated spherically charge-stabilized dispersions (described and characterized elsewhere) of colloidal silica Ludox HS (Grace, \( \sim 220 \) \( m^2/g \)) with radius of 8 nm,\(^ {52} \) Levasil (Azko-Nobel, \( \sim 30 \) \( m^2/g \)) 46 nm,\(^ {53} \) latex \( (\sim 20 \) \( m^2/g \)) 142 nm,\(^ {54} \) and microsuspensions containing particles with a radius of \( 0.5 \mu m \) \( (\sim 3 \) \( m^2/g \)), 2.5 \( \mu m \) \( (0.5 \) \( m^2/g \)), and 5 \( \mu m \) \( (\sim 0.2 \) \( m^2/g \), Sigma-Aldrich), respectively. The drying of droplets with particle concentrations of 1, 2, 3, 5, 10, 20, and 30 wt % were investigated with varying droplet volumes of 0.8, 1.1, 1.4, 1.7, 2, and 2.3 \( \mu L \). The drops were inserted into the standing wave using a 5 \( \mu L \) syringe. The chamber is ventilated with a flow rate of 0.5 l/min of air during the course of the evaporation to ensure constant drying conditions.\(^ {55} \) An automatic imaging system was set up to record every minute the temporal evolution of the droplet during drying using a complementary metal oxide semiconductor (CMOS) camera (Canon EOS 700D). The resulting images were manually processed using ImageJ software. The aspect ratio, being the ratio between horizontal and vertical diameter, and the change in equivalent droplet diameter were calculated during drying. In particular, the cross-sectional area of the droplet, \( A \), was computed from the images, and the equivalent diameter, \( d \), was calculated using \( d = \frac{4A}{\pi} \). Each experiment was repeated five times to ensure reproducibility of the data and improve statistics. The resulting dried grains were collected and subjected to scanning electron microscopy (SEM) imaging (Quanta 200) which enabled us to investigate the morphology and surface characteristics of the final grains as a function of the size and concentration of suspended particles.

4. RESULTS AND DISCUSSION

4.1. Single Droplet Drying Behavior. A series of images illustrating qualitatively how the droplets evolve as drying proceeds is shown in Figure 3. The drying behavior of silica–water suspensions initially resembles that of a pure droplet, i.e., a constant decrease in the volume as the bulk of the liquid is evaporated. At the end of drying of micro- and nanosuspensions, a solid grain is formed.

Using the recorded images, we could quantify the temporal evolution of each drop (Figure 4). Contrary to the case of drying of pure water droplets, solvent evaporation from suspensions leads to shell formation. In such situations, droplet shrinking ceases at a certain diameter corresponding to the size.
of the dried grain. The results obtained show how the evaporation rates from the droplet suspension are modified as particle concentration changes. Note that each experiment was conducted 5 times, but because the standard deviation between experiments was small and the data was robustly reproducible, to improve the clarity the error bars were not added to Figure 4. The drying behavior of droplets containing lower particle concentrations is quite close to that of a pure water droplet. However, as the concentration of suspended particles increases, the duration of the stage-1 drying decreases. This is attributed to the presence of less water in the droplet leading to an earlier formation of the final grains.

The evaporation rate (i.e., the slope of the line in Figure 4) was relatively constant in the case of nanosized particle dispersion probably because of the narrow ranges of the concentrations. However, in the case of microsuspension droplets, as particle concentration increased, slightly higher evaporation rates during stage-1 were observed. These results seem to be consistent with other research which found the presence of particles enhanced the evaporation of small droplets.56,57 This is explained by particles near the interface such that part of the particles along the air–water interface, covered by liquid, are exposed into the ambient air and the remaining part is partially submerged in the liquid. This enhances the evaporation rate (possibly due to the enhanced vaporization surface) as has been shown in Zhang et al.56 It is therefore to be expected that droplets containing higher particle concentration at the interface would have a slightly higher evaporation rate, as seen in Figure 4.

In addition to the equivalent droplet diameter, the evolution of the aspect ratio (AR) over time in the case of droplets containing micro- and nanosized dispersions was measured as presented in Figure 5. We observed significant deviation from sphericity toward the end of the drying of droplets containing microparticles (Figure 5b). Such an increase in AR was not observed in the case of nanosuspension. SEM analysis of the obtained grains shows that a half apricot-like morphology is typically formed from the drying of microsuspensions. This is shown in Figure 6a,b. However, in the case of nanosuspensions, the droplets maintain their shape and shrink isotropically during the evaporation process, forming an agglomerated spherical grain as presented in Figure 6c. During drying, instabilities can arise as a result of capillary forces which are applied through a relatively thin layer in the shell. Such deformation occurs as soon as the outer shell is capable of responding as an elastic solid (i.e., high enough yield stress) and can lead to instabilities that cause buckling.58,59 As buckling involves a mix of compression and expansion regions, it is often associated with additional fracturing, as observed in Figure 6d.
as rigidity is also the prerequisite for fracture. Thus, it is clear from the captured images of the final dried grains coupled with SEM analysis that the morphology and surface characteristics are significantly influenced by the size and concentration of the suspended particles. The governing mechanism is further explained in the following section.

4.2. Influence of Particle Size on Grain Properties. We have estimated the Péclet number for drying of micro- and nanosized dispersions in our experiments using eqs 1 and 2. For \( T = \sim 23 ^\circ \text{C}, r \sim 2.5 \mu \text{m}, \) and \( \eta = 9.33 \times 10^{-4} \text{ Pa s} \) (assuming viscosity of pure water at \( T \sim 23 ^\circ \text{C} \)), the Stokes–Einstein diffusivity for microsilica particles is estimated as \( 9.3 \times 10^{-14} \text{ m}^2/\text{s} \), which results in \( Pe \cong 5000 \) for a drying time of \( \sim 1200 \text{ s} \). The large \( Pe \) value indicates preferential particle accumulation at the interface between liquid and air, making it more susceptible to deformation, which is indeed in agreement with the SEM images of the grains formed at the end of drying of microsuspensions presented in Figure 6a,b. The formation of hollow grains from droplet drying is generally the result of formation of an internal void during the first drying period, which depends on the ability of the particles to diffuse inside the droplet.\(^6^0,6^1\) In this case, the diffusivity of the particles is dependent on the particles size: microparticles have a much lower diffusion coefficient than nanoparticles and therefore cannot diffuse easily to the center of the droplet, as illustrated in Figure 2e–h. In addition to the hollow shape, the presence of shear bands can also be seen on the surfaces of the dried grains (Figure 6a).\(^5^2\)

In the case of nanosuspensions, with particles of radius 8 nm, the diffusion coefficient is estimated to be \( 3.33 \times 10^{-11} \text{ m}^2/\text{s} \) with the corresponding \( Pe \cong 14 \). Therefore, in the case of drying of nanosuspension, the relatively small \( Pe \) value indicates that the diffusive transport is comparable with the convective transport. This should result in homogeneous particle distribution and deposition during drying which eventually leads to an agglomerated dense spherical grain (Figure 2a–d), which is in agreement with the SEM images of the grain formed at the end of drying of nanosuspension at low concentrations presented in Figure 6c.

However, during drying of nanosuspension droplets containing high particle concentration, buckling and fragmentation of the grains may occur (Figure 6d). In such cases, the buckling of a colloidal droplet can be reduced by forming a suspension of aggregates by increasing the ionic strength such that it leads to a reduction in the magnitude and range of the repulsive electrostatic energy, thus inducing aggregation between particles.\(^6^3\) Drying experiments were performed with nanoparticles (30%) in a NaCl salt solution (0.2 M) which resulted in solid grains with cracks on the surfaces clearly visible, as shown in Figure 7. The reduction in the buckling of the grains is due to an increase in the permeability of the shell to solvent which is in agreement with the results of previous studies by Lintingre et al.\(^6^4\)

4.3. Péclet Number and Morphology. The experimental parameters of particle size, droplet volume, and particle concentrations were all observed to influence the final grain shape. Here we systematically alter each parameter and record the drying dynamics. Figure 8 shows the final grain obtained from the drying of droplets with varying (a) particle size \( (V_0 = \) 1.4 \( \mu \text{L} \)) and (b) droplet volume (PS = 0.5 \( \mu \text{L} \)).
1.4 μL) and (b) initial droplet volume (r = 0.5 μm) plotted against the observed aspect ratio. From this, we can see a clear morphological transformation from spherical to half apricot dried grains. Small particles, i.e., low Pe, leads to spherical grains as diffusive transport dominate convection, thus, the particles tend to homogenize over space, and the droplets shrink isotropically to form a uniform spherical grain illustrated in Figure 8a. Larger particles lead to the formation of hollow grains which is driven by the inhomogeneity of the shell. Similarly, larger droplets, i.e., higher Pe, hollow grains are formed and smaller droplets tend to form grains that remain intact, i.e., not hollow. The transition stage, i.e., between spherical and half apricot morphology, occurs in the intermediate Pe range in which the obtained solid grains have an AR of ∼1.3 similar to an elongated grain in shape (as seen in Figure 8b in the lower range of Pe).

Predicting the morphology of the final grains formed as a result of drying of suspension based on the value of Péclet number will be useful to provide an effective representation of the primary forces determining the shape of the final grains. Similar to the classification of flow regimes based on the Reynolds number in fluid mechanics, the pattern formation in fractal fluid dynamics, or the classification of displacement patterns during multiphase flow in porous media, such a characteristic diagram will provide guideline to associate specific shapes of final grains to a given range of Péclet numbers. To obtain such a characteristic diagram, we combine these experimental data into a dimensionless Péclet number to show that the drying behavior is dependent on all the parameters (i.e., r, V0, and X0) and that the data all collapse when plotted against Pe.

The phase diagram illustrating the relationship between the particle aspect ratio and the Pe is presented in Figure 9. It shows one can accurately predict the shape of the dried colloidal droplet based on Pe. Note that the closer the AR is to 1, the closer is the shape of final particle to a perfect sphere. The points plotted in Figure 9 include experimental results adopted from Mondragon et al. where the Pe was estimated for initial droplet volumes of 0.7 and 0.07 μL. In their experiments, the 0.07 μL droplets contain two different concentrations, which results in two Pe numbers, because of the effects of particle concentration on the drying rate and consequently drying time (using eqs 1 and 2). For T = 363.15 K, r ~ 6.5 μm, and η = 3.15 × 10⁻⁴ Pa·s (assuming viscosity of pure water at 363.15 K), the diffusion coefficient is estimated as 1.3 × 10⁻¹³ m²/s, which results in Pe = 36 000 and 6 400 for the drying time of ∼75 and 65 s, respectively. The morphology of the final dried grains obtained deviates significantly from sphericity, as seen in the measured aspect ratio (see Figure 3a,b from Mondragon et al.). Thus, we show that our characteristic diagram can be used to accurately predict the final grains obtained from the drying of droplet suspensions. For example, here we would expect smaller particle size with low Pe to form grains in the transition stage, i.e., elongated but not hollow grains (similar to that observed in Figure 8b). A further decrease in these parameters would lead to the formation of spherical grains. Interestingly, this mechanism is relatively independent of the stress–strain, or constitutive, relationship of the drying droplet. If a rigid shell forms, it will start thin. As thin shells are most prone to buckling, it will buckle, regardless of the exact details of its elastic response. The data collapse that we showed in Figure 9, involving three different types of particles with different elastic properties, confirms the fundamental nature of this response.

5. SUMMARY AND CONCLUSION

The drying of a suspension and the associated grain morphology formed as a result of drying is a function of a number of parameters including, but not limited to, particle size, particle concentration, and droplet volume. The aim of the present work was to investigate the drying kinetics of droplet suspensions and the resulting morphology of grains at the end of drying, which is important to a variety of industrial applications. Single-droplet drying experiments were performed using an acoustic levitator and a CMOS camera to record the temporal evolution of the drying droplets as a function of suspended particle size and concentration. SEM was used to observe the characteristics of the final dried grain obtained at the end of each experiment. We show that the drying behavior and the assembly of the final grains are significantly influenced by the particle size, particle concentration, and initial droplet volume. The observed morphological difference was shown to be the result of the competition between diffusion and convection during drying. We combine these experimental data into a dimensionless Péclet number to show that the drying behavior is dependent on all the parameters. This resulted in a novel characteristic diagram which allows one to accurately predict the shape of the dried colloidal droplet based on Pe.
