The grown lead iodide (PbI₂) is usually two-dimensional sheets with a finite size which necessitate sophisticated device metallization and the growth of quasi one-dimensional materials is still challenging. In this work, large-size (length > 100 μm), single-crystalline and high-density PbI₂ nanobelts are successfully synthesized by manipulating the microenvironment in a two-step vapor deposition process at a slow heating rate of ~18 °C min⁻¹. Firstly, PbI₂ nanosheet seeds are grown by physical vapor deposition, and then PbI₂ nanobelts are synthesized by a self-catalyzed vapor-liquid-solid growth mechanism, which is verified by the Pb nanoparticles on the nanobelts tips. Photoluminescence and ultraviolet-visible spectra show the uniform high-quality crystallinity of the as-prepared large-size PbI₂ nanobelts with a bandgap of 2.36 eV. When configured into photodetectors with a shadow mask, the fabricated device exhibits a low dark current of 4 pA, an impressive ON/OFF current ratio of 10³ ~ 10⁴, a photoresponsivity of 13 mA W⁻¹, and a fast response with the rise and decay time constants of 425 and 41 ms, respectively. All these performances are comparable to those of state-of-the-art of layered PbI₂ nanostructures photodetectors, but the ease of synthesizing large-size PbI₂ nanobelts may have useful impact on next-generation easily-fabricated high-performance optoelectronics.

Introduction

In the past decade, layer-structured materials with in-plane covalent bonding and weak interlayer interactions (van der Waals) have attracted extensive research attentions, owing to the possibility of thinning down to atomically thick two-dimensional (2D) materials.¹⁻¹³ As a typical layered perovskite derivative, lead iodide (PbI₂) has attracted extensive research attention in solar cells, photodetectors and other optoelectronic devices,¹⁴⁻²⁶ due to its direct bandgap of 2.28-2.5 eV and tunable optoelectronic properties.^{16, 19-27} Layered PbI₂ material is composed of covalently bonded I-Pb-I repeating units stacked along the c-axis by van der Waals interlayer interaction.^{28, 29} Up to now, low dimensional PbI₂ nanostructures of nanosheets,^{19-22, 24, 26} nanowires^{19, 23, 27} and atomically thin monolayers²² have been prepared by a simple synthesis method of vapor deposition. In the reported vapor deposition of PbI₂ nanostructures, one-dimensional (1D)

nanowires followed a chemical vapor deposition (CVD) process,^{19, 23, 27} otherwise, two-dimensional (2D) nanosheets followed a physical vapor deposition (PVD) process.^{19, 21, 22, 26} For example, Meyers et al. reported recently the self-catalyzed vapor-liquid-solid (VLS) growth of PbI₂ nanowires in a CVD growth procedure.²³ On the other hand, highly uniform 2D PbI₂ nanosheets have been prepared by Wang et al. via a space confined PVD process.²⁶ Furthermore, Lan et al. pointed out that the surface roughness of the growth substrates played a critical role on the nucleation of PbI₂ microplanes in a PVD growth of 2D PbI₂ nanosheets.²¹ However, for photodetector application, 1D nanowires have a relatively smaller absorption area leading to low current density and 2D nanosheets with a finite size necessitate complicated device metallization such as Au nanowire mask method.^{19, 22} Therefore, it is highly desirable to synthesize large-size 2D materials for easily fabricated photodetectors.

Combining the geometry of 1D nanowires with 2D nanosheets, quasi 1D nanostructure of 2D nanobelt is considered as a promising candidate for achieving high performance and easily fabricated optoelectronic devices. Up to now, most of the works are concentrated on the 2D morphologies with grain size on the order of tens of micrometers,^{19, 22, 24, 26} there are limited reports focusing on the large-scale synthesis of 2D PbI₂ nanobelts with size up to hundreds of micrometers in a CVD process. With a size up to hundreds of micrometers, it will become easy to handle the authentic optoelectronic applications of 2D nanomaterials. In this work, large-scale PbI₂ nanobelts with length up to hundreds of micrometers (>100 μm) have been prepared successfully on amorphous SiO₂/Si substrates via a

two-step thermal evaporation process. Firstly, the hexagonal layered PbI_2 nanosheets are formed on the growth substrate when the source material of PbI_2 is at a low thermal temperature, following a PVD growth process. With the increase of the heating temperature, PbI_2 nanobelts grow from the as-grown PbI_2 nanosheet seed layer by a self-catalyzed CVD process. The mass of the source material, growth temperature and growth time are found to be the essential issues on the controllable growth of large-size and high-density PbI_2 nanobelts. Without adopting any sophisticated device fabrication process, the as-prepared larger-size PbI_2 nanobelts can be configured into the simple photoconductors by shadow mask, exhibiting impressive photosensing properties with a small dark current of 4 pA, an impressive ON/OFF current ratio of $10^3 \sim 10^4$, and a good responsivity of 13 mA W^{-1} at a wavelength of 445 nm, an excellent stability and an efficient time response (i.e., rise and decay time constants of 425 and 41 ms, respectively). All these results confirm evidently the technological potency of these large-size and highly crystalline 2D PbI_2 nanobelts for easily-fabricated high-performance photodetectors.

Experimental

PbI_2 nanobelts synthesis

Large-size PbI_2 nanobelts studied here were synthesized by employing a solid-source CVD method in a horizontal tube furnace, similar to the reported literatures.^{19, 21–23, 26, 27, 30–32} In brief, the solid source of PbI_2 powder (99.99% purity) was located in the upstream and the growth substrate of SiO_2/Si was located in the downstream of a two-zone tube furnace with a distance of 5.5 cm. Argon (99.999% purity) was used as the carrier gas to transport the thermally vaporized material to the downstream. Prior to heating, the quartz tube was purged with 50 standard cubic centimeter (sccm) Ar for 0.5 h. During growth, the source material of PbI_2 was heated to 550 °C in 30 min ($\sim 18 \text{ }^\circ\text{C min}^{-1}$) and was kept at this temperature for 20 min. As shown in the temperature distribution of downstream zone (Fig. S1, ESI. †), the growth temperature of the large-size PbI_2 nanobelts is deduced as $\sim 364 \text{ }^\circ\text{C}$. After growth, heating of PbI_2 was stopped and cooled to room temperature naturally in the Ar flow. Eventually, a layer of orange yellow product could be collected on the substrate.

Materials characterization

Surface morphologies of the as-grown large-size PbI_2 nanobelts were examined using a scanning electron microscope (SEM, Nova NanoSEM 450, FEI Company) and a transmission electron microscope (TEM, FEI TECNAI 20). The thickness of the as-prepared large-size PbI_2 nanobelts were measured by atomic force microscope (AFM, CSPM5500, Being Nano-Instruments). The crystal structure and crystallinity of the products were verified by X-ray diffraction (XRD, D8 Advance, Bruker) and selected area electron diffraction (SAED) attached to TEM. Elemental identifications were performed using an energy dispersive x-ray spectroscopy (EDS) detector attached to SEM to measure the chemical composition of the obtained nanobelts.

For the TEM studies, the nanobelts were scratched onto the copper grid for the corresponding characterization. Raman and Photoluminescence (PL) spectra followed PL and Raman mappings were measured by a Raman spectrometer (inVia Reflex, Renishaw) with 532 nm laser and 325 nm laser, respectively. Corresponding absorption spectrum was measured using UV-vis spectrometer (TU-1901, Beijing Puxitongyong Company), which was converted to absorbance spectra ($\alpha = -\ln(r)$, where B is a film thickness related coefficient).

Nanobelts devices fabrication and photo-electrical property measurements

For the device fabrication, the nanobelts were firstly transferred onto the degenerately doped p-type Si substrates with a 300 nm thick thermally grown gate oxide layer by using a physical dry transfer technique. Stainless steel grid was next used as the shadow mask and attached onto the substrate. Ti (5 nm) and Au (200 nm) thin films were deposited via electron beam evaporation as the electrical contact electrode. The electrical performance of the fabricated device was then characterized with a standard Lakeshore electrical probe station and a Keithley 4200 semiconductor analyzer. Laser diodes with wavelength of 375, 445, 532, 630 and 730 nm were used as light source for the photodetector measurement, while the power of the incident irradiation was tuned and measured using a power meter from 15 to 150 mW cm^{-2} .

Result and discussions

SEM together with EDS technology are adopted here to characterize the morphology and composition of the as-prepared larger-size PbI_2 nanobelts. With an optimal growth condition of 0.015 g PbI_2 powder as source material, larger-size PbI_2 nanobelts with high density have been prepared successfully on amorphous substrate at 550 °C for 20 min in a 50 sccm Ar atmosphere. As shown in Fig. 1a, the as-grown sample shows a morphology of nanobelt with a smooth surface and a length of $>100 \text{ }\mu\text{m}$. At the same time, the composition of this large-size nanobelt is detected by EDS, showing the nanobelt body consists of Pb and I elements in the atomic ratio of 1:2. As shown in Fig. S2, ESI. †, the thickness of the as-prepared large-size PbI_2 nanobelts is measured as $287 \pm 94 \text{ nm}$ by AFM. Furthermore, the smooth surface of the as-prepared PbI_2 nanobelts is also verified by TEM in Fig. 1b. SAED pattern in the inset displays the characteristic hexagonal symmetry of diffraction spots with the zone axis of [0001], suggesting that the nanobelts are grown in the $\langle 01\bar{1}0 \rangle$ direction with an excellent crystallinity. Based on the XRD pattern of Fig. 1c, the as-prepared PbI_2 nanobelts is the hexagonal PbI_2 structure (JCPDS: 07-0235) without any other impurity phases, indicating the nanobelts being pure PbI_2 crystals.^{16, 21} This is in line with the SAED result. It is worth pointing out that nanospheres are found at the tip of the as-prepared nanobelts (Fig. 1d), indicating the as-prepared nanobelts follow a VLS growth mechanism.^{33, 34} It is a common phenomenon of nanoparticles existing on the as-prepared PbI_2 nanobelts, as shown in Fig. S3,

Fig. 1 Morphology, microstructure and composition characterization of the as-prepared large-size PbI_2 nanobelts. ESI.†. The sizes of the observed nanoparticles are 200–1200 nm. The detailed growth mechanism of this kind of large-size PbI_2 nanobelts will be discussed later. As presented in Fig. 1e & f, the EDS elemental mapping of the same nanobelts (inset of Fig. 1d) illustrates the homogeneous distribution of Pb and I atoms along the nanobelts body. In the meanwhile, it is found that the tip mainly contains Pb atom, whereas the I content drops drastically once passing the tip/nanobelt interface, as shown in Fig. S4, ESI.†. In short, all these demonstrate the well-controlled surface morphology, crystallinity and stoichiometry of PbI_2 nanobelts achieved with a simple vapor deposition growth technique.

For guiding the controllable growth of large-size 2D nanomaterials, the growth mechanism of the as-prepared PbI_2 nanobelts is studied in detailed by issues of the mass of source material, growth temperature, and growth time. As shown in SEM images of Fig. 2, one can see that the mass of PbI_2 plays an important effect on the as-prepared PbI_2 morphology. With a low content of 0.005 g PbI_2 powder, only nanosheets are found on the substrate. When the mass of PbI_2 powder reaches 0.01 g, large-size PbI_2 nanobelts with low density can be observed, possibly caused by the inadequate PbI_2 or Pb/I vapor during the nanobelt growth process. Afterwards, as the mass of PbI_2 powder exceeds the optimal content of 0.015 g, there are small nanosheets grow on the surface of the large-size PbI_2 nanobelts, as marked by red circles in Fig. 2c&d. In a word, as PbI_2 has a relatively low melting point of 406 °C,³⁵ it evaporates easily to form the vapor phase precursors. Therefore, too little source such as 0.005 g would be all evaporated to form the nanosheets, leading to no successive nanobelt growth. While higher source mass would provide not only the precursors for nanosheet but also the nanobelt growth. On the other hand, the effect of growth temperature on the controllable growth of PbI_2 nanobelts is also studied and the corresponding morphology can be found in Fig. S5, ESI.†. Namely, at a low growth temperature of 490 °C, nanosheets dominated the morphology of the as-grown sample. With the increase of growth

Fig. 2 Effect of source material mass on the nanobelts growth. (a, b, c, d) SEM images of the as-prepared PbI_2 samples grown with different source material masses of 0.005, 0.01, 0.05 and 0.1 g.

temperature, the amount of nanobelts increases. However, the width of these as-grown nanobelts is narrow, possibly caused by the inactive PbI_2 or Pb/I vapor. In the end, the growth time is also found to be a significant element on the controllable growth of large-size PbI_2 nanobelts, as shown in Fig. 3. With a growth time of 1 min, nanosheets together with very short nanobelts are observed on the substrate. When the growth time prolongs to 5 min, large-size PbI_2 nanobelts with very low density are prepared. Importantly, with a high-resolution SEM images, one can see that the nanobelts are grown from the nanosheets randomly. That is, some nanobelts are parallel to the nanosheets and the others are tilted to the nanosheets. The tilt angle can be estimated from XRD pattern in Fig. 1c, where the dominant peaks are related to c-plane of PbI_2 while only a weak peak attributed to (201). Therefore, it is plausible that most nanobelts tilt at an angle of $\sim 75^\circ$ which is the one between (201) and (001) planes. It is worth pointing out that the success control growth of the large-size PbI_2 nanobelts is benefited from the slow heating rate (reach 550 °C in 30 min) of the source material. With a rapid heating rate of the source material (reach 550 °C in 7 min), there are only nanoparticles on the substrate (shown in Fig. S6, ESI.†). Anyway, this phenomenon of nanostructures growing from its seed layer is usually found in the growth process of other kinds of nanomaterials.^{36–39} In a word, by adopting an optimal growth condition of 0.015 g PbI_2 powder evaporated at 550 °C for 20 min, high-quality and large-size PbI_2 nanobelts with a high density can be prepared on the amorphous SiO_2/Si substrate.

Based on the above discussion, a possible growth mechanism can be proposed here, as shown in Fig. 3e–h. With a slow heating rate of source material, the growth of large-size PbI_2 nanobelts can be divided into two stages. At the first stage, PbI_2 nanosheets grow on the smooth substrate by a PVD process, as reported elsewhere.^{19, 21, 22, 26} Namely, at a low growth temperature, the new coming PbI_2 species would get adsorbed on the PbI_2 nuclei as well as on the substrate surface and then be migrated to the growth sites. Similar to the other types of layered materials, the growth sites of layered PbI_2 nanosheets are always located at the edges as illustrated in Fig. 3e. As a

Fig. 3 Possible growth mechanism of the as-prepared large-size PbI_2 nanobelts. (a, b) SEM images of PbI_2 sample grew at 550 °C for 1 min; (c, d) SEM images of PbI_2 sample grew at 550 °C for 5 min; (e, f, g, h) Schematic illustration of the possible growth process of the as-prepared large-size PbI_2 nanobelts.

result, PbI_2 nuclei would then be expanded in the in-plane direction and grown into a large sheet-like structure, as shown in Fig. 3f. With the increase of growth temperature, the evaporated PbI_2 would mostly be decomposed into elemental or molecular Pb and I species. Pb has a higher boiling point of 1749 °C,⁴⁰ but a low melting point of 327.4 °C;⁴⁰ therefore, it is possible for Pb species to aggregate into Pb liquid droplets during the growth. This result has been verified by the EDS mapping of the as-prepared PbI_2 nanobelts in Fig. 1e-f. Consequently, the PbI_2 nanobelts can then be grown after the catalytic supersaturation of PbI_2 in the Pb liquid droplets via VLS mechanism. However, with a rapid heating rate of source material, there is not abundant time for the PVD growth of seed layer of PbI_2 nanosheets on the substrate, and thus no nanobelts can be prepared (Fig. S6, ESI.†). With a low content of source material, PbI_2 powder would be evaporated off at the first stage of nanosheets growth, resulting in insufficient source vapor for the nanobelts growth. In this case, only nanosheet can be found on the substrate, as shown in Fig. 2a. With an excessive source material, the third PVD/CVD growth process of PbI_2 nanobelts started at the smooth surface of the as-grown large-size PbI_2 nanobelts. As a result, many irregular nanosheet/nanobelts are observed on the surface of the large-size nanobelts (shown in Fig. 2c&d). In case of growth temperature, only PVD growth process occurs at a low growth temperature, and the as-prepared sample shows nanosheets with a few of nanobelts (shown in Fig. S5a, ESI.†). However, with the increase of growth temperature, the decomposition of PbI_2 occurred and the contents of Pb and I vapor increase simultaneously, resulting in the success growth of large-size PbI_2 nanobelts (shown in Fig. S5b-d, ESI.†). In short, with a slow heating rate of source material, high-quality, high-density and large-size PbI_2 nanobelts have been prepared successfully from a seed layer of PbI_2 nanosheets by a VLS growth mechanism in a two-step thermal evaporation process.

Raman, UV-vis absorption and PL spectra are carried out to investigate the optical properties of the as-prepared large-size PbI_2 nanobelts. The Raman data of the PbI_2 nanobelts excited by a 532 nm wavelength laser is recorded in Fig. 4a. Three dominant Raman peaks are clearly observed at the location of 73.8, 97.2, and 112.7 cm^{-1} , corresponding to the E_g , A_{1g} , and A_{2u} Raman vibration modes in 2H polytype of PbI_2 , respectively.^{20, 26, 41, 42} Similar with the reported 2D PbI_2 nanostructures, the peak intensity of the as-prepared large-size PbI_2 nanobelts is

Fig. 4 Optical properties of the as-prepared large-size PbI_2 nanobelts. (a, b, c) Raman, UV-vis absorption and PL spectra of the as-prepared PbI_2 nanobelts, respectively. Inset of Figure c is the 2D PL mapping image at the tip of the as-prepared nanobelt.

strong and the corresponding peak's full width at half-maximum (FWHM) is small,^{19-22, 24, 26} indicating a high crystal quality. UV-vis absorption spectrum is employed to study the bandgap of the as-prepared large-size PbI_2 nanobelts. The experimental values of the bandgap can be obtained through a Kubelka-Munk (K-M) transformation of the UV-visible spectrum: $[F(R)hv]^2$, where $F(R)$ is the diffuse reflectance spectrum.⁴³⁻⁴⁵ As shown in Fig. 4b, the calculated bandgap of PbI_2 nanobelts is about 2.36 eV, which coincides well with the previous reports.^{16, 19-22, 24-27} In addition to Raman and UV-visible spectra, room temperature PL spectrum of the as-prepared large-size PbI_2 nanobelts is also obtained, as shown in Fig. 4c. The sharp peak centered at 514 nm (2.41 eV) is in perfect agreement with the bandgap of 2.36 eV determined from the UV-visible spectrum. The strong peak intensity and the narrow FWHM of the PL peak further verify the high crystalline quality of the as-grown large-size PbI_2 nanobelts. This result also can be deduced from the 2D PL mapping image of the as-prepared large-size PbI_2 nanobelts. As depicted in the inset of Fig. 4c, the color contrast of PL mapping is very uniform, indicating the uniform crystallinity of the large-size PbI_2 nanobelts. It is noticeable to point out that there is no 2D PL mapping signal from the Pb nanoparticle, resulting in a black zone at the top of the as-prepared PbI_2 nanobelt, as shown in Fig. S7, ESI.†. This phenomenon also can be found in 2D Raman mapping at a frequency of 97.2 cm^{-1} (PbI_2 domain). However, in Fig. 4c, owing to the low resolution, the black sphere zone of the Pb nanoparticle is so small that it cannot be

Fig. 5 Photoresponse of the as-prepared large-size PbI_2 nanobelts photodetectors. seen clearly. In short, all these results strongly suggest the potential application of the as-prepared large-size PbI_2 nanobelts with high crystallinity for high-performance optoelectronic devices.

As a direct bandgap semiconductor, besides the understanding of growth kinetics and mechanisms, it is interesting to assess the optoelectronic properties of the as-prepared large-size PbI_2 nanobelts. In this case, photodetector is fabricated on the SiO_2/Si substrate by a simple shadow mask process (Si substrate

with a 300 nm SiO_2 insulating top layer) and is electrically characterized under illumination. Fig. 5a is the SEM image of the as-fabricated photodetector with a PbI_2 nanobelt area of $879.8 \mu\text{m}^2$. Inset is the atomic model of PbI_2 crystal, displaying PbI_2 is a layered material, which composed of covalently bonded I–Pb–I repeating units stacked along the c-axis and the van der Waals interlayer interaction. Fig. 5b is the device schematic of the as-fabricated photodetector. Under illumination, electron-hole will generate and transform in the semiconductors. As shown in Fig. S8, ESI†, the current linearly increase with the voltage in current-voltage (I–V) curves, indicating good Ohmic contacts between the Au electrodes and PbI_2 nanobelts. At a bias voltage of 5 V, the photocurrents of the as-fabricated photodetector are shown in Fig. 5c under different incident light wavelength with an intensity of 35 mW cm^{-2} . With an illumination laser wavelength smaller than the bandgap of the as-prepared PbI_2 nanobelts (514 nm), the photocurrent increases with the increase of laser wavelength. On the other hand, no photocurrent can be detected when the illumination laser wavelength is larger than 514 nm. Hence, the 445 nm laser is selected to illuminate the photodetector for better understanding the photosensing behavior of the PbI_2 nanobelts. The dependence of its photocurrent on different light intensities is measured and depicted in Fig. 5d. It is well known that the measured data can be well fitted by Equation of $I_p = \alpha\Phi^\beta$, where I_p is the photocurrent, α and β are the fitting parameters, and Φ is the light intensity.^{46–51} As a result, the as-fabricated photodetector reveals a power dependence of $I_p = 0.23\Phi^{0.799}$ from the fitting of the measured data, depicting the sublinear relationship between the photocurrent and light intensity, which is often observed in layered-material based photoconductors due to the complex processes of electron-hole generation, trapping, and recombination in the semiconductors.^{46–48} It is worth to point out that the value of β is higher than the reported 2D nanosheets in literatures,^{19, 21, 22} indicating the high crystallinity of the as-prepared PbI_2 nanobelts. Furthermore, two important figure of merits, responsivity (R) and detectivity (D^*), are the key parameters for

Table 1 Comparison of various figure of merits of different representative 2D layered PbI_2 based photodetectors.

evaluating the sensitivity of the as-fabricated photodetector. R is defined as the photocurrent generated per unit power of incident light on the effective area of a photodevice, and D^* reflects the photodetector's sensitivity. R and D^* can be calculated by the following equations: $R = I_p(\Phi S)^{-1}$ and $D^* = RS^{1/2}(2eI_d)^{-1/2}$, where I_p is the photocurrent, Φ is the light intensity, S is the active area of the photodetector, e is the absolute value of the charge of an electron, and I_d is the dark current.⁵²⁻⁵⁵ For the large-size PbI_2 nanobelts based photodetector, the maximum R and corresponding D^* are calculated to be about 13 mA W^{-1} , and 3.048×10^{10} Jones across the entire measured range, respectively, comparable to the graphene photodetectors ($0.5\text{--}6.1 \text{ mA W}^{-1}$)^{56, 57} and the single-crystal $CdTe$ nanosheets (0.6 mA W^{-1}).⁵⁸ The repeatability and response speed are another two essential parameters for the performance assessment of photodetectors. The repeatability can be appraised by measuring the photocurrent as a function of time (i.e., I - t curves) under chopped illumination in Fig. 5e. It is obvious that the device ON- and OFF-state can be effectively modulated by the chopped illumination with a good repeatability and an impressive ON/OFF current ratio of $10^3 \sim 10^4$. It is worth pointing out that the photodetector also has a low dark current of 4 pA when the laser is on the "OFF" state. The low value of dark current indicates a low noise and a high sensitivity, which are vital for the practical electric-devices. In addition, a high-resolution I - t curve is then utilized to study the response speed of the photodetector. Usually, the time needed for the current to increase from 10% to 90% of the peak value and vice versa are defined as the rise time and decay time constants, respectively.^{59, 60} Based on the measurement presented in Fig. 5f, the rise and decay time constants can be identified as 425 and 41 ms accordingly, implying the high quality of the as-prepared large-size PbI_2 nanobelts. Regardless, all these obtained performance indicators of nanobelts detectors are highly comparable to those of state-of-the-art PbI_2 as reported in the recent literature (Table 1), illustrating the impressive performance and promising prospect of our large-size PbI_2 nanobelts for the highly-efficient photodetection. It is worth pointing out that the rise and decay times are related to the recombination of nonequilibrium photo-generated carriers. The combination processes can be affected by many factors, such as trap density, trap energy level in the forbidden gap, surface states, and adsorbed molecules, etc. Those factors are not only related to the quality of the photosensing materials, but also related to device fabrication processes. Although our PbI_2 nanobelts have high quality, the device fabrication processes can also degrade the performance of the response speed. Further optimizations of device fabrication process are needed in the future.

Conclusions

In conclusion, large-scale synthesis of large-size PbI_2 nanobelts are successfully demonstrated by manipulating the source materials mass, growth temperature, and growth time on amorphous Si/SiO_2 substrate in a two-step vapor deposition

process. With a slow heating rate of the growth temperature, PVD growth process of PbI_2 nanosheets occurs firstly, followed by a CVD growth of large-size PbI_2 nanobelts at a higher growth temperature by using the as-grown PbI_2 nanosheets as a seed layer. The results of SAED and PL measurements confirm highly uniform, high-quality crystallinity of the as-prepared large-size PbI_2 nanobelts. The as-prepared PbI_2 nanobelts based photodetector exhibits a low dark current of 4 pA, an impressive ON/OFF current ratio of $10^3 \sim 10^4$, a photoresponsivity of 13 mA W^{-1} , and a fast response with the rise and decay time constants of 425 and 41 ms, respectively, with a large area PbI_2 nanobelt of $879.8 \text{ } \mu\text{m}^2$. All the discussed parameters reveal the technological potency of these large-size PbI_2 nanobelts for next-generation high-performance optoelectronics.

Notes

Zai-xing Yang and Ning Han conceived and designed the research. Mingming Han grew the nanobelts. Jiamin Sun implemented the XRD measurement and analysis. Mingming Han and Luozhen Bian performed the SEM, PL and Raman measurement and analysis. Jiamin Sun and Luozhen Bian measured UV-vis absorption and analysis. Mingming Han, Jiamin Sun and Luozhen Bian carried out the device fabrication. Zhou Wang contributed to photodetection test. Lei Zhang was dedicated to TEM measurement. Yanxue Yin, Zhaofeng Gao and Fulin Li contributed to data analysis of TEM and photodetection. Zai-xing Yang, Ning Han, Qian Xin, Longbin He and Aimin Song prepared the manuscript with the help from all of the other co-authors.
