Abstract: Oxide growth plays a critical role in the failure mechanisms of thermal barrier coating (TBC) systems. This study is aimed to investigate the chemo-mechanical coupling oxidation behavior of CoNiCrAlY coating which is widely used as bond coat in TBC systems. Oxidation experiments at 1000 °C were conducted on both load-free and tension-loaded specimens. Microscopic examination was also performed using scanning electron microscopy and Raman spectroscopy. The experimental results show that the oxidation of the CoNiCrAlY coating was accelerated by the applied tensile load. In the oxide scale of the load-free specimen, both α -alumina and θ -alumina were present when the oxidation duration was short (≤ 15 hours), but the θ -alumina transformed to α -alumina after 20-hour oxidation. By contrast, in the tension-loaded specimen, mixed α -alumina and θ -alumina were found even after oxidation for 20-60 hours. This phenomenon suggests that the tensile load can cause delay in the phase transformation from fast-growing θ -alumina to slow-growing α -alumina. A new mechanism based on the theoretically derived effect of mechanical work on the free energy for alumina phase transformation has been proposed to explain the experimental observations.

transformation, thermal barrier coatings

1. Introduction

Thermal barrier coating (TBC) systems are the main constituent parts of hot end components of turbine blades in modern gas turbines, and they comprise three layers at least, i.e. ceramic top coat (TC), metallic bond coat (BC) and superalloy substrate [1-5]. Thermally grown oxide (TGO) is an additional thin layer formed between BC and TC, as a result of BC oxidation during the service of TBC systems. In the long-term operation of a gas turbine, the TGO continues growing, and consequently it alters the local interface morphology and generates significant stresses, which act as an important driving force of cracking at the interfaces and surface in TBC systems [6-8]. Therefore, it is important to understand the high temperature oxidation behavior of BC (i.e. the TGO growth) in TBC systems.

Previous experimental studies on oxidation in TBC systems were carried out mainly for load-free BC layer sprayed on planar test piece (mainly on wafer) and then oxidized at high temperature; the research attention was placed to the microstructure, the spraying process, the surface treatment before the oxidation and so on [9-11]. The growth behavior of the TGO between BC and TC was also studied [12-14] in a way similar to that for the specimens without TC. Different aspects of the oxidation behavior have been examined. For instance, material scientists are mainly interested in the oxidation mechanism and the growth rate of an oxide film, while mechanics are devoted to simplifying oxidation process so as to predict the oxide growth stress and

the associated crack initiation and propagation at the oxide/substrate interface, for the development of a series of failure theories [15-18]. It thus appears that the current understanding of the oxidation process of BC in TBC systems is decoupled between chemistry and mechanics. By contrast, in other similar areas of research, such as lithium batteries, it has been found that some chemical reaction phenomena are actually associated with the stress state, which acts as a chemical reaction condition and affects the chemical reaction rate [19-21]. Therefore, it is believed also necessary to examine the potential chemo-mechanical coupling during TGO growth in order to better understand the oxidation behavior of BC and its associated failure mechanisms of TBC systems.

Despite the paucity of experimental studies on the chemo-mechanical oxidation behavior of metallic coatings, the effect of stress state on oxidation of metals/alloys is a research topic of lasting significance and interest. For instance, in 1978, Evans et al. [22] reported experimental observations showing that long-term oxidation weight gain of Zircaloy-2 changed from following the classic parabolic law to cubic law, and they asserted that the significant compressive stress developed during oxidation decelerated the oxidation reaction and proposed a chemo-mechanical coupling mechanism to account for this effect. Recently, some theoretical studies on the chemo-mechanical coupling oxidation behavior of metals/alloys have been also reported [23-27], which focused on the effect of stresses developed without external mechanical load. In parallel, experiments were also conducted to examine the effect of applied load on the oxidation

behavior of metals/alloys. For instance, Takei and Nii [28] investigated the oxidation of Ni-20Cr-4Al alloy under tensile load and they found that different tensile loads could cause different oxide exfoliation areas, thereby eventually leading to different weight gain. Calvarin-Amiri et al. [29] investigated the effect of tensile load on the oxidation of Ni-20Cr alloy and they found that the tensile load accelerated high-temperature oxidation and the oxidation products were different between the specimens with and without tensile load. Zhou et al. [30-32] investigated the oxidation of pure nickel and Fe-20Cr alloy under compressive load, and the oxidation of pure nickel under both tensile and compressive loads; they concluded that: (1) the oxidation reaction can be accelerated by both tensile and compressive loads; (2) the grain size can be reduced under mechanical loading; and (3) the grain boundary density can be increased such that it would enhance the diffusion of oxygen ions. More recently, high-temperature three-point bending experiments have been carried out to study the oxidation of MoCu superalloy under tensile and compressive loads [33], and the results showed that tensile stress accelerated high-temperature oxidation, whereas compressive stress had opposite effect, which were explained via theoretically deriving the effect of stress on ion diffusion.

The previous research, as reviewed above, has shown the significant difference in oxidation behavior between the load-free metals/alloys and those under tensile/compressive loads. In this study, the oxidation behavior of CoNiCrAlY coating (i.e. typical BC in TBC systems) is investigated experimentally and theoretically.

Section 2 deals with the details about the experiment. The results and discussion are presented in Section 3 and Section 4, respectively. Concluding remarks are made in Section 5.

2. Materials and method

Fig. 1. Geometric configuration of the specimen (dimension in mm).

Ni-based superalloy plates (K465) were used as the substrates for spraying Co-32Ni-21Cr-8Al-0.5Y (wt.%) coatings. The superalloy plates were cut into dog bone shape via wire electrical discharge machining. The Chinese standard GB/T 2039-1997 was followed, and the specimen dimension was 126×25×3 mm. Fig. 1 shows the details about the geometrical configuration of the specimen. High velocity oxy-fuel (HVOF) was used to deposit a 150- μ m thick CoNiCrAlY coating in the middle region of the specimen (i.e. dark part as shown in Fig. 1). It should be noted that the CoNiCrAlY coating was sprayed on both sides of the specimen and no surface treatment was

performed. For simplicity, the ceramic TC in TBC systems was not considered in this study.

High-temperature creep machine (Jilin GuanTeng) was employed to provide uniform heating and apply tensile load to the specimen simultaneously. The test temperature was 1000 °C with a heating rate of 10 °C/min and the tensile load was 900 N (corresponding to a nominal tensile stress of 30 MPa). The maximum oxidation duration was 60 h at the exposure temperature. Every 20 h the specimen was cooled in the air to the room temperature and then the weight was measured using an accurate balance with 0.1-mg sensitivity (METTLER TOLEDO ME204). After the step of weighing, the specimen was analyzed by scanning electron microscopy (SEM, FEI Quanta 200) with energy dispersive spectroscopy (EDS). The oxidation weight gain was divided by the total area of the surfaces (i.e. both sides of the specimen) on which the CoNiCrAlY coating was deposited, and then the ratio was squared, such that a parabolic oxidation kinetics law can be conveniently revealed by examining the linearity of the relationship between the squared weight gain per area and oxidation time.

3. Results

Fig. 2 shows the relation between the squared weight gain per area and the oxidation time of the coating specimen. The overall trend of the measurement data is similar, whether a tensile load is applied or not, and the relation does not deviate much from the parabolic law of oxide growth. However, it is evident that more oxides were formed

when the tensile load was applied, and consequently the oxide growth rate was increased by 20%.

Figs. 3 and 4 show the oxide microstructure on the surface of the coating specimen, as observed in SEM images. Comparing the results shown in Figs. 3 and 4, different oxidation products can be clearly seen for different oxidation time and load conditions. As shown in Fig. 3, for the load-free specimen, the oxidation products were regular oxide grains. Distinctive microstructures developed in the tension-loaded specimen; i.e. blade, whisker or needlelike oxidation products were observed in Fig. 4. These two types of oxides were analyzed by energy dispersive spectrometer (EDS), as shown in Figs. 5 and 6. The chemical compositions of all the oxidation products are dominated by Al and O (Figs. 5b and 6b). Therefore, the two types of oxidation products, as shown in Figs. 3 and 4, are actually different phases of alumina. It has been recognized that θ -alumina usually grows with a bladelike, whisklike or needlelike morphology, while the α -alumina grows to form a dense equiaxed microstructure [34-37]. It is thus clear that the regular oxide phase, as shown in Fig. 3, is α -alumina, whereas the bladelike oxide phase, as shown in Fig. 4, is θ -alumina. Fig. 4 also indicates that the proportion of the bladelike oxide phase, i.e. θ -alumina, reduced with the oxidation time increasing.

4. Discussion

4.1. Theoretical analysis

It has been mentioned in Section 1 that previous experimental results showed an acceleration effect of applied tensile load on oxidation rate of some metals and alloys at high temperature [29, 32, 38], and our experimental results for CoNiCrAlY coating, as presented in Fig. 2, are consistent with these previous observations. Such accelerated oxidation was prevalently explained as a result of the effect of stress on ion diffusion, e.g. the tensile stress enables more oxygen ions to cross the oxide layer which acts as an oxidation barrier and finally more metal ions underneath the oxide layer are oxidized. By contrast, herein we propose another mechanism to explain the tensile-stress enhanced oxidation phenomenon for the CoNiCrAlY coating.

In the CoNiCrAlY coating, alumina is the dominant oxide formed, as shown in Figs. 5 and 6, because Al is the most reactive element. The Al oxidation generates

metastable oxide first, e.g. θ -alumina, and then it transforms to a stable oxide, i.e. α -alumina. Eventually the oxide is only composed of α -alumina. It has been widely recognized that the coefficient of the growth rate of θ -alumina is much larger (even two orders larger in magnitude) than that of α -alumina [37, 39-41]. From Figs. 3 and 4, it is clearly seen that the development of different phases of alumina is affected by the tensile load. Consequently, the oxidation rates are significantly different (Fig. 2) due to the effect of tensile load on alumina phase transformation. We observed both θ -alumina and α -alumina in the tension-loaded specimen, but only α -alumina in the load-free specimen for the same oxidation time (Figs. 3-6). The θ -alumina gradually disappeared with oxidation time increasing, and the transformation from θ -alumina to α -alumina was retarded when the tensile load was applied, as shown in Figs. 3 and 4 (additional short-duration oxidation experiment has been also conducted to verify this, see Section 4.2). Therefore, we propose a new mechanism that the tensile load accelerates the oxide growth via its effect on phase transformation, as schematically shown in Fig. 7.

Fig. 7. Schematic diagram of θ - to α -alumina phase transformation process [42]. The crystal structural parameters are $a=1.17$ nm, $b=0.57$ nm, $c=1.12$ nm, $\beta=103.34^\circ$ for θ -alumina and $a=0.47$ nm, $b=0.47$ nm, $c=1.29$ nm for α -alumina.

Similar to the previous theoretical model of the effect of tensile load on martensitic transformation [43, 44], we present the following theoretical analysis of the effect of tensile load on alumina phase transformation during the oxidation of CoNiCrAlY coating. As a general model, both volumetric and distortional deformation is considered. Provided that the parent phase is subjected to uniaxial stress when the phase transformation occurs, the free energy change under uniaxial stress is

$$\Delta G_\sigma = \tau \Delta \gamma_0 + \sigma \Delta \varepsilon_0 \quad (1)$$

where τ and σ are the shear and normal components of the uniaxial stress, respectively, as decomposed on the habit surface for the phase transformation; $\Delta \gamma_0$

and $\Delta\varepsilon_0$ are the change of the shear strain along the habit surface and the change of dilation strain after phase transformation, respectively.

Decomposition is performed using the Mohr Circle, i.e.

$$\tau = 0.5\sigma_1 \sin 2\theta \quad (2)$$

$$\sigma = \pm 0.5\sigma_1(1 + \cos 2\theta) \quad (3)$$

Incorporating above equations into Eq. (1) we obtain

$$\Delta G_\sigma = 0.5\sigma_1\Delta\gamma_0 \sin 2\theta \pm 0.5\sigma_1(1 + \cos 2\theta)\Delta\varepsilon_0 \quad (4)$$

The $\pm$ appears since the parent phase can be subjected to either tensile or compressive stress (tension is positive), and σ_1 stands for the absolute value of the uniaxial stress.

Along a particular angle, the $d\Delta G_\sigma$ reaches maximum, i.e.

$$\frac{d\Delta G_\sigma}{d\theta} = \sigma_1\Delta\gamma_0 \cos 2\theta \pm \sigma_1(-\sin 2\theta)\Delta\varepsilon_0 = 0 \quad (5)$$

when $\tan 2\theta = \pm\Delta\gamma_0 / \Delta\varepsilon_0$. If the specimen is subjected to hydrostatic pressure:

$$\Delta G_\sigma = -\sigma_1\Delta\varepsilon_0 \quad (6)$$

In this study, the specimen was only subjected to uniaxial tensile stress, so we have $\Delta G_\sigma = 0.5\sigma_1\Delta\gamma_0 \sin 2\theta + 0.5\sigma_1(1 + \cos 2\theta)\Delta\varepsilon_0$ and $\tan 2\theta = \Delta\gamma_0 / \Delta\varepsilon_0$. Since the θ - to α -alumina transformation is a volume reduction process [45, 46], we have $\Delta\varepsilon_0 < 0$. If $\Delta\gamma_0 < 0$, then $\tan 2\theta > 0$, i.e. $\sin 2\theta > 0$ and $\cos 2\theta > 0$, thus $\sigma_1\Delta\gamma_0 \sin 2\theta < 0$

and $\sigma_1(1 + \cos 2\theta)\Delta\varepsilon_0 < 0$. Eventually we have $\Delta G_\sigma < 0$. In contrast, if $\Delta\gamma_0 > 0$, then $\tan 2\theta < 0$, i.e. $\sin 2\theta < 0$ and $\cos 2\theta > 0$, thus $\sigma_1\Delta\gamma_0 \sin 2\theta < 0$ and $\sigma_1(1 + \cos 2\theta)\Delta\varepsilon_0 < 0$, and eventually we still have $\Delta G_\sigma < 0$. If the phase transformation does not introduce additional shear strain and only involves the change of dilation strain, we can always decompose the volumetric strain into vertical and parallel to the direction of the uniaxial tension. So $\Delta\varepsilon_0$ is the change of volumetric strain along the direction of tensile stress, while the volumetric strain perpendicular to the direction of the uniaxial tensile load does not contribute to the change in free energy, and again, we have $\Delta G_\sigma = \sigma_1\Delta\varepsilon_0 < 0$. Therefore, ΔG_σ is always less than zero if tensile stress is present, no matter how much $\Delta\gamma_0$ is.

The total free energy change associated with the phase transformation consists of two parts, viz.

$$\Delta G = \Delta G_{che} - \Delta G_\sigma \quad (7)$$

where ΔG_{che} is the free energy change with chemical origin. As this phase transformation is spontaneous, the ΔG_{che} is less than zero. Learning from the analysis presented earlier, we obtain $\Delta G_\sigma < 0$, so at last, we have $0 > \Delta G > \Delta G_{che}$. In other words, the tensile stress slows down the phase transformation from θ -alumina to α -alumina, because the less decrease in the free energy causes slower phase transformation.

If the specimen was subjected to compressive stress, same analysis method could be applied and in such a case we find that $\Delta G_\sigma > 0$. Then we obtain $0 > \Delta G_{che} > \Delta G$, so

the compressive stress accelerates the phase transformation from θ -alumina to α -alumina.

4.2. Short-duration oxidation

In the main experiments presented in Section 3, no microscopic morphology typical for θ -alumina was observed in the load-free specimen that was exposed to high temperature for 20-60 h. This result may suggest that the θ -alumina has already transferred to α -alumina before the microstructural examination was performed. To verify this, we conducted an additional short-duration oxidation experiment as follows.

The same K465 superalloy was used to prepare coating specimen. But for the additional experiment, the specimen was a disk with edge chamfering (2.54 cm in diameter and 3 mm in thickness). The same proportion of CoNiCrAlY powder was used to spray a 150- μ m thick coating on the disk using the same parameters for the HVOF process, without any surface treatment. The specimen experienced oxidation in the furnace (MTI KSL—1700X) at same high temperature of 1000 °C. The microscopic morphology of the oxidation product was observed by SEM (FEI Quanta 200) when the oxidation lasted for 5 h, 10 h, 15 h and 20 h. Then we used the Raman spectroscopy (HORIBA JOBIN YVON) to analyze the chemical composition of the oxide for the oxidation time of 5 h and 20 h. The wavelength of the excitation of the Raman spectroscopy was 476 nm and the power of the laser was 10 mW. It should be mentioned that Raman spectroscopy is a suitable method to analyze the components of the thin

oxide layer because of the non-destructiveness and the small depth of laser (about dozens of nanometers). As the metal does not have any Raman peak, the collected signals all come from the oxide.

Fig. 8 shows the microstructures of the oxidation products without any mechanical load. It is clearly seen that θ -alumina was formed in the 5-h oxidation product but absent in the 20-h oxidation product. The θ -alumina was also observed in the SEM images of specimens oxidized for 10 h and 15 h. Raman spectroscopy was used to further examine the constituent phases. The Raman spectroscopy characteristic peak of θ -alumina is about 220 cm^{-1} , and the peak of α -alumina is about 420 cm^{-1} [47, 48]. It is evident that the oxide that formed after 5-h oxidation comprises both θ -alumina and α -alumina, while the oxide formed after 20-h oxidation comprises only α -alumina. So this additional experiment confirms the conclusion reached in section 4.1, i.e. the specimen without mechanical load initially produced θ -alumina before the first 20-h oxidation reaction, but with oxidation continuing, the θ -alumina transferred into α -alumina and eventually θ -alumina disappeared after 20-h oxidation.

Fig. 8. Microscopic surface morphology of the additional coating specimen (disk wafer) without mechanical load after oxidation for 5 h (a) and 20 h (b).

Fig. 9. Raman spectra obtained from two additional coating specimens (disk wafer) without mechanical load after oxidation for 5 h.

Fig. 10. Raman spectra obtained from two additional coating specimens (disk wafer) without mechanical load after oxidation for 20 h.

5. Concluding remarks

The chemo-mechanical coupling oxidation behavior of CoNiCrAlY coating is investigated by means of high temperature (1000 °C) experiment and theoretical model. The oxidation time ranged from 5 h to 60 h in experiments on both load-free and tension-loaded specimens. A chemo-mechanical coupling mechanism based on alumina phase transformation has been proposed to explain the experimental observation. The observations and conclusions are summarized as follows.

1. The oxidation rate of CoNiCrAlY coating was accelerated by tensile load (applied nominal tensile stress equal to 30 MPa).
2. The oxidation products were composed of both α -alumina and θ -alumina for high temperature oxidation time of 20 h / 40 h / 60 h under tensile load, and similar oxide microstructure was observed in the load-free specimen under short-duration oxidation (≤ 15 h). By contrast, only α -alumina was formed in the load-free specimens after oxidation for 20 h or longer. This suggests that the tensile load can retard phase transformation from θ -alumina to α -alumina.
3. It has been theoretically demonstrated that the phase transformation from θ -alumina to α -alumina can be slowed down due to the effect of the mechanical work exerted by applied tensile load on the free energy, and consequently the tensile load can accelerate the oxide growth in the CoNiCrAlY coating since θ -alumina has much higher growth rate than α -alumina.

Graphical abstract

Highlights

- Chemo-mechanical coupling oxidation behavior is investigated experimentally and theoretically
- New mechanism based on effect of mechanical work on phase transformation is proposed
- Tensile load accelerates oxidation of CoNiCrAlY coating at high temperature
- Transformation from fast-growing θ -alumina to slow-growing α -alumina is retarded by tensile load
