Performance Analysis of Uplink SCMA with Receiver Diversity and Randomly Deployed Users

Jinchen Bao, Zheng Ma, Member, IEEE, Ming Xiao, Senior Member, IEEE, Zhiguo Ding, Senior Member, IEEE, and Zhongliang Zhu

Abstract—This paper considers the performance analysis of sparse code multiple access (SCMA) with receive diversity arrays and randomly deployed users in a cellular uplink scenario. The impact of path-loss on the performance of SCMA is characterized, by assuming independent Rayleigh fading and joint maximum likelihood (ML) receivers. A tight upper bound on the probability of symbol detection error is derived, and show that a diversity order which is equal to the product of the number of receive antennas and the signal-space diversity can be achieved, and the large-scale path-loss decreases only the coding gain.

Index Terms—Sparse code multiple access (SCMA), maximum likelihood (ML) detection, randomly deployed users.

I. INTRODUCTION

SPARSE code multiple access (SCMA) techniques have attracted significant interests in academia and industry, and have been proposed for the fifth generation (5G) wireless networks [1]-[2]. Many aspects relating SCMA have been studied recently, typical examples including the multiuser detection design [3] [4], multidimensional codebooks construction [5]. However, the research works on the performance analysis of SCMA are very limited. This is partially because it is difficult to deal with the multidimensional sparse constellations involved in the multiuser scenarios. In particular, the error performance of uplink and downlink SCMA with maximum likelihood (ML) multiuser detection was analyzed in [6], and a similar analysis was presented in [7] for uplink SCMA with multiple receive antennas. However, only small-scale Rayleigh fadings were investigated.

This work is an extension of [6] to a large-scale fading environment, and the aim is to characterize the impact of path-loss on the performance of SCMA. In particular,

II. SYSTEM MODEL

We consider a single-cell uplink transmission scenario in which J users/layers and a BS are deployed within a cell, where each user employs only one SCMA layer. The BS, located at the center of the cell, is equipped with N receive antennas and the antenna elements are spaced far enough to ensure independent path-loss, and the users with a single antenna are uniformly distributed within the cell, as shown in Fig. 1. The message from the j-th user is mapped into a K-dimensional symbol, denoted as x_j, and x_j = [x_j[1], · · · , x_j[K]]^T, which is transmitted over K independent channels, e.g. orthogonal frequency division multiplexing (OFDM) tones. The channels between the J users and the BS are denoted by the NK × KJ channel gain matrix

\[ H = \begin{bmatrix} \text{diag}(h_{1,1}) & \cdots & \text{diag}(h_{1,J}) \\ \vdots & \ddots & \vdots \\ \text{diag}(h_{N,1}) & \cdots & \text{diag}(h_{N,J}) \end{bmatrix}, \] (1)
where $h_{j,n} = [h_{j,n}[1], \ldots, h_{j,n}[K]]^T$, is the $K$-channel vector between the $j$-user and the $n$-th antenna of the BS. Its component satisfies $h_{j,n}[k] = g_{j,n}[k]/d_j^\alpha$, where $g_{j,n}[k] \sim CN(0,1)$, represents a Rayleigh fading coefficient, $d_j$ is the distance between the BS and the $j$-th user, and $\alpha$ is the path-loss exponent. Here we assume that the distance remains constant during a $K$-dimensional symbol period. The path-loss model assumes that the received power decays as $|h_{j,n}[k]|^2$ during a symbol period.

The observed signal vector at the BS is given by

$$y = \sum_{j=1}^{J} \sqrt{p_j} E_s H_j x_j + n = \sqrt{E_s} H X + n,$$

where $E_s$ is the total transmitting power for $J$ users, $p_j$ is the power allocation coefficient satisfying $\sum_{j=1}^{J} p_j = 1$, $H_j = [\text{diag}(h_{j,1}), \ldots, \text{diag}(h_{j,N})]^T$, is the channel corresponding to the $j$-th user, $X = [\sqrt{p_1} x_1, \ldots, \sqrt{p_J} x_J]^T$, is the combined codeword for $J$ users. The additive white Gaussian noise (AWGN) vector, with independent and identically distributed (i.i.d) components, is denoted as $n$, $n \sim \mathcal{C}\mathcal{N}(0, N_0)$. Therefore, the multiple access channel can be viewed as an equivalent linear system.

Let $\phi_k = \{j|1 \leq j \leq J, x_j[k] \neq 0\}$, which denotes the index of users that transmitting over the $k$-th channel. With perfect channel estimation at the BS, the Euclidean distance metric of the joint ML detector for $X$ is given by

$$\hat{X} = \arg \min_{\hat{X}} ||y - \sqrt{E_s} H \hat{X}||.$$

### III. Error Probability Analysis

Assume that the codebook size is $C$ and equiprobable transmission for each user is realized, the union bound on the SER for the $j$-th user is given by [6]

$$P_j(e) \leq \frac{1}{C^J} \sum_{X} \sum_{x_j \neq \hat{x}_j} P\{X \rightarrow \hat{X}\},$$

where $P\{X \rightarrow \hat{X}\}$ is the PEP that the detector mistakes $X$ with $\hat{X}$, and $\hat{x}_j$ is the symbol component for the $j$-th user corresponding to $\hat{X}$.

We first define the following column vectors

$$x[k] = \text{Vec}[[\sqrt{p_j} x_j[k] | j \in \phi_k]],$$

$$h_n[k] = \text{Vec}[[h_{j,n}[k] | j \in \phi_k]],$$

$$g_n[k] = \text{Vec}[[g_{j,n}[k] | j \in \phi_k]],$$

$$d[k] = \text{Vec}[[d_j | j \in \phi_k]].$$

In the following, we will determine the PEP according to two types of $d_j$:

a) Case I: users with fixed distances such that $d_j$ remain constants all the time;

b) Case II: the users are randomly distributed within the cell such that $d_j$ are i.i.d. RVs, while $d_j$ remain constants during a $K$-dimensional symbol period.

#### A. Case I: Users with Fixed Distances

For the linear system in (3), the PEP between $\hat{X}$ and $X$ can be calculated as [9]

$$P\{X \rightarrow \hat{X}\} = \Pr\{\Delta < 0\} = \frac{1}{2\pi} \int_{c-i\infty}^{c+i\infty} \Phi_\Delta(s) \frac{ds}{s},$$

where $c$ is a positive number to move the integration path away from the singularity at $s = 0$,

$$\Delta = ||y - \sqrt{E_s} H \hat{X}||^2 - ||y - \sqrt{E_s} H X||^2 = E_s||H(X - \hat{X})||^2 + 2\sqrt{E_s}Re\{n^H (H(X - \hat{X}))\},$$

and $\Phi_\Delta(s)$ is the Laplace transform of the PDF of $\Delta$. Note that $\Delta$ is a real Gaussian RV conditioned on $H$, namely $\Delta \sim \mathcal{C}\mathcal{N}(\mu E_s,2\mu E_s N_0)$ with $\mu = ||H(X - \hat{X})||^2$, then

$$\Phi_\Delta(s) = E_\Delta H e^{-s\Delta} = E_\Delta H e^{-s(1-sN_0)E_s \mu}.$$  

(9)

In (9), $\mu$ can be further expressed as

$$\mu = \sum_{n=1}^{N} \sum_{k=1}^{K} |h_{n}[k]|^2 \left(\langle x[k], \hat{x}[k]\rangle - \langle \hat{x}[k], \hat{x}[k]\rangle\right)^2$$

$$= \sum_{n=1}^{N} \sum_{k=1}^{K} g_{n}[k]^2 (\text{diag}(d[k]))^{-\alpha} \left(\langle x[k], \hat{x}[k]\rangle - \langle \hat{x}[k], \hat{x}[k]\rangle\right)^2$$

$$= \sum_{n=1}^{N} \sum_{k=1}^{K} \rho_{k,n},$$

where $\rho_{k,n} = |g_{n}[k]|^4 e[k]^2$. Let

$$\tau_k = ||e[k][j]| = \sum_{j \in \phi_k} p_j d_j^{-\alpha} |x_j[k] - \hat{x}_j[k]|^2.$$  

(10)

Since $g_{n}[k] \sim \mathcal{C}\mathcal{N}(0, I)$, $g_{n}[k]^2 e[k] \sim \mathcal{C}\mathcal{N}(0, \tau_k)$. So, $\rho_{k,n}$ are independent exponential RVs with mean $\tau_k$. Therefore,

$$\Phi_\Delta(s) = \prod_{n=1}^{N} \prod_{k=1}^{K} \mathcal{E}_{\rho_{k,n}} e^{-s(1-sN_0)E_s \mu} = \prod_{k=1}^{K} \mathcal{E}_{\rho_{k,n}} e^{-s(1-sN_0)E_s \mu}$$

$$= \prod_{k=1}^{K} \left[\frac{1}{1 + s(1-sN_0)E_s \tau_k}\right]^N,$$

and then, the PEP is given by

$$P\{X \rightarrow \hat{X}\} = \frac{1}{2\pi} \int_{c-i\infty}^{c+i\infty} \prod_{k=1}^{K} \left[\frac{1}{1 + s(1-sN_0)E_s \tau_k}\right]^N \frac{ds}{s}.$$  

(13)
To investigate the diversity order, we analyze the asymptotic performance using a Chernoff bound estimation for the PEP, which also gives us insights on the performance improvement. The Chernoff bound on the PEP is given by [9]

$$P_{ch}(X \rightarrow \tilde{X}) = \min_{q>0} \Phi_{\Delta}(q),$$  
(14)

where $q$ is a real variable. Minimizing $\Phi_{\Delta}(q)$ over $q$ is equivalent to maximize $\Psi(q) = \prod_{k=1}^{K} [1 + q(1 - qN)E_s \tau_k]$, whose derivative over $q$ is given by

$$\frac{d\Psi(q)}{dq} = (1-2qN)E_s \sum_{k=1}^{K} \tau_k \prod_{j=1, j\neq q}^{K} [1+q(1-qN)E_s \tau_j].$$  
(15)

Obviously, $q = \frac{E_s}{2N}$ leads to a local maximum of $\Psi(q)$ and hence a local minimum of $\Phi_{\Delta}(q)$. Note that $\Phi_{\Delta}(q)$ is a positive convex function whose minimum is unique [10], then,

$$P_{ch}(X \rightarrow \tilde{X}) = \Phi_{\Delta}\left(\frac{1}{2N}\right) = \prod_{k=1}^{K} \left(1 + \frac{E_s}{4N_0} \tau_k\right)^{-N}. \tag{16}$$

At large signal to noise ratio (SNR) where $\frac{E_s}{4N_0} \tau_k \gg 1$, by using the approximation $(1 + x)^{-1} \approx \frac{1}{x}$, it holds

$$P_{ch}(X \rightarrow \tilde{X}) \approx \left[\frac{E_s}{4N_0} \prod_{k=1, \tau_k \neq 0}^{K} \tau_k \right]^{-N} \tilde{G}_{d}(X, \tilde{X}), \tag{17}$$

where $\tilde{G}_{d}(X, \tilde{X})$ is the number of nonzeros in $\tau_1, \cdots, \tau_K$. Let $G_d$ and $G_c$ be the minimum of $\tilde{G}_{d}(X, \tilde{X})$ and $\tilde{G}_{c}(X, \tilde{X})$ over all the codeword pairs $X$ and $\tilde{X}$, respectively. Then, all the PEPs decay with the slope of $(E_s/N_0)^{-NG_d}$ and the system achieves a diversity order $NG_d$. The diversity is in two-fold: the $N$ receiving antennas contribute a diversity of $N$, and $G_d$ is the signal-space diversity coming from the use of the multidimensional constellation [11]. Due to the sparseness of the codebooks, the signal-space diversity is always less than $K$. Compared with the small-scale fading where $d_j = R_0$, the large-scale path-loss preserves the diversity but reduces $G_c$, which is generally referred to as the coding gain [12].

In general, the nearest neighbors among the multiuser codeword pair $(X, \tilde{X})$ dominate the performance in the large SNR region, and they correspond to the maximum PEP and hence the minimum of $\tilde{G}_{c}(X, \tilde{X})$ and $\tilde{G}_{d}(X, \tilde{X})$. So, $G_c$ and $G_d$ are achieved when $X$ and $\tilde{X}$ are the nearest codewords to each other, for which only one user’s symbol pair corresponding to $X$ and $\tilde{X}$ are different. If only $x_j$ and $\tilde{x}_j$ are distinct in the multiuser codeword pair $(X, \tilde{X})$,

$$\tau_k = p_j d_j^{-\alpha} |x_j[k] - \tilde{x}_j[k]|^2,$$  
(18)

and $\tilde{G}_{d}(X, \tilde{X}) = \tilde{w}_d(x_j, \tilde{x}_j)$, where $\tilde{w}_d(x_j, \tilde{x}_j)$ is the Hamming distance between the multidimensional symbols $x_j$ and $\tilde{x}_j$. Then

$$\tilde{G}_{c}(X, \tilde{X}) = p_j d_j^{-\alpha} \left( \prod_{k=1, x_j[k] \neq \tilde{x}_j[k]}^{K} |x_j[k] - \tilde{x}_j[k]|^2 \right)^{1/\tilde{w}_d(x_j, \tilde{x}_j)},$$  
(19)

Therefore, by minimizing over all the users $(j)$ and all symbol pairs $(x_j, \tilde{x}_j)$, it holds that

$$G_d = \min_{\forall x \neq \tilde{x}} G_{d}(X, \tilde{X}) = \min_j w_{d,j},$$

$$G_c = \min_{\forall x \neq \tilde{x}} G_{c}(X, \tilde{X}) \approx \min_j \min_{w_{c,j}, w_{d,j}} p_j d_j^{-\alpha} \tilde{w}_c(x_j, \tilde{x}_j),$$  
(20)

where

$$w_{c,j} = \min_{\forall x \neq \tilde{x}} \tilde{w}_c(x_j, \tilde{x}_j),$$

$$w_{d,j} = \min_{\forall x \neq \tilde{x}} \tilde{w}_d(x_j, \tilde{x}_j),$$  
(21)

which are the normalized minimum product distance and the minimum Hamming distance for the $j$-th user’s codebook, respectively [11]. It is implied in (20) that the performance of SCMA is dominated by the individual user’s codebook with the worst performance.

To improve the performance of SCMA, a useful guidance is to optimize the power allocation strategy or the multiuser codebooks, such that the coding gain and the signal-space diversity are maximized. We take the power allocation as an example. Under the condition of $\sum_{j=1}^{J} p_j = 1$, $G_c$ is maximized when

$$p_j = p_j d_j^{-\alpha} \frac{d_{j}}{\sum_{j=1}^{J} d_{j}}, \quad \text{for } j = 1, \cdots, J.$$  
(23)

In most cases, the multiuser codebooks are built from a common mother constellation [1] such that their fundamental properties are the same, then $w_{c,j}$ and $w_{d,j}$ are the same for all the codebooks. Therefore, from $\sum_{j=1}^{J} p_j = 1$, it is easy to get that

$$p_j = \frac{d_j}{\sum_{j=1}^{J} d_j}, \quad \text{for } j = 1, \cdots, J.$$  
(24)

Obviously, $p_j$ is inversely proportional to the power attenuation, and the solution also assures the fairness among the multiple users in terms of achievable error performance. As for the codebooks optimization, a reliable criterion is to maximize the signal-space diversity ($w_{d,j}$) and the minimum product distance ($w_{c,j}$) of the mother constellation. Such a problem has been well solved by the linear constellation precoding scheme [14] [15], where unitary transformations can be used over a given mother constellation to increase both the diversity and coding gains.

B. Case II: Users with Random Distances

In this case, the PDF of the variable $d$ in (2) is given by [16]

$$f(d) = \left\{ \begin{array}{ll}
\frac{2\pi d}{Q^2} & \text{if } \frac{Q}{2} - 2 \arccos \left( \frac{\sqrt{2} R_0}{Q^2} \right) \leq d \leq \frac{Q}{2}, \\
0 & \text{otherwise,}
\end{array} \right.$$

where $Q = 3\sqrt{3} R_2^2 / 2 - \pi R_0^2$. Then, the RV $\mu$ in (9) has a different distribution as that in Case I. Let’s define the parameter

$$\hat{\lambda}_k = \|x[k] - \check{x}[k]\|^2 = \sum_{j \in U_k} p_j |x_j[k] - \check{x}_j[k]|^2,$$  
(25)

This is similar to the concatenated spherical codes [13], where the optimal concatenation satisfies that the scaled minimum distances are the same for all the component codes. The proof is given in Lemma 3.6 of [13].
and the unitary vector \( f[k] = \frac{1}{\sqrt{\lambda_k}}(x[k] - \hat{x}[k]) \). Then, \( \mu \) can be expressed as

\[
\mu = \sum_{n=1}^{N} \sum_{k=1}^{K} |h_n[k]|^2 |f[k]|^2 = \sum_{n=1}^{N} \sum_{k=1}^{K} \lambda[H_n[k] \cdot f[k]]^2. \tag{26}
\]

It is difficult to determine the distribution of \( |h_n[k]|^2 |f[k]|^2 \), since \( h_n[k] |f[k] \) is a weighted sum of several i.i.d. RVs. As \( f[k] \) is unitary, we assume that \( h_n[k] |f[k] \) has the same distribution as the elements in \( h_n[k] \). The assumption is based on the fact that the performance is dominated by the PEPs of nearest neighbors of codewords, it corresponds to the smallest multiuser distances and for which a very small number of users are involved in \( f[k] \). With joint detection, the approximation becomes more accurate in the large SNR region. Since in this case, the number of erroneously detected users is small and if only one user is in error, there will be only one nonzero element in \( f[k] \) and the assumption comes true. Then, we assume \( h_n[k] |f[k] \approx \hat{g}_{n,k} \sqrt{\frac{2}{N}} \), where \( \hat{g}_{n,k} \sim CN(0,1) \) and \( \hat{d} \) has the same distribution as \( df \). Thus,

\[
\mu \approx \hat{d}^{-\alpha} \sum_{n=1}^{N} \sum_{k=1}^{K} \lambda[H_n[k] \cdot \hat{g}_{n,k}]^2 = \hat{d}^{-\alpha} V. \tag{27}
\]

In the following, we determine the PDF of \( \mu \). Let \( \lambda = [\lambda_1, \ldots, \lambda_M]^T \), denoting the \( M (M \leq K) \) distinct values in the set \( \{ \lambda_1, \ldots, \lambda_K \} \), and \( r = [r_1, \ldots, r_M]^T \), denoting the number of entries in \( \{ \lambda_1, \ldots, \lambda_K \} \) that are equal to \( \lambda_1, \ldots, \lambda_M \) and times \( N \), respectively. Since \( \hat{g}_{n,k} \sim CN(0,1) \), \( V \) is a weighted sum of \( NK \) exponential RVs, which is generalized Chi-squared distributed with PDF given by [6][17]

\[
f_V(v) = A_{r,\lambda} \prod_{m=1}^{M} \sum_{r_m=1}^{r_m} \frac{B_{m,r_m,\lambda}}{r_m!} \Gamma(r_m!-e^{-v/r_m}), \tag{28}
\]

where \( A_{r,\lambda} = \prod_{m=1}^{M} \lambda_m^{-r_m} \) and

\[
B_{m,r_m,\lambda} = (-1)^{r_m+1} \prod_{j \in \Omega_{m,l}} \left( \eta_j + r_j - 1 \right) \cdot \eta_j \prod_{j \in \Omega_{m,l}} \left( \frac{1}{\lambda_j} - 1 \right)^{(r_j+\eta_j)}, \tag{29}
\]

for which \( \eta = [\eta_1, \ldots, \eta_M]^T \), which is chosen from the set \( \Omega_{m,l} \) given by

\[
\Omega_{m,l} = \left\{ \eta \in \mathbb{Z}^M : \sum_{j=1}^{M} \eta_j = l-1, \eta_m = 0, \eta_j \geq 0 \forall j \right\} \tag{30}
\]

Similar as that in [16], from (2), (24) and (27), we can derive the PDF of \( \mu \) as

\[
f_\mu(\mu) = \frac{4\pi}{3\sqrt{3}R^2} \left[ \frac{R_0^{a+2}}{2} f_V(R_0^a \mu) + \int_{R_0}^{R} t^{a+1} f_V(t^a \mu) dt \right] - \frac{6}{\pi} \int_{\frac{\sqrt{3}R}{2t}}^{\frac{R}{t}} t^{a+1} \arccos \left( \frac{\sqrt{3}R}{2t} \right) f_V(t^a \mu) dt. \tag{31}
\]

Then, the Laplace transform in (9) is given by

\[
\Phi_\Delta(s) \approx \int_0^\infty e^{-s(1-sN_0)E_s} f_\mu(\mu) d\mu = \frac{4\pi}{3\sqrt{3}R^2} \left[ \frac{R_0^{a+2}}{2} \chi(s, R_0^a) + \int_{R_0}^{R} t^{a+1} \chi(s, t^a) dt \right] - \frac{6}{\pi} \int_{\frac{\sqrt{3}R}{2t}}^{\frac{R}{t}} t^{a+1} \arccos \left( \frac{\sqrt{3}R}{2t} \right) \chi(s, t^a) dt, \tag{32}
\]

where

\[
\chi(s, t^a) = \int_0^\infty e^{-s(1-sN_0)E_s} f_{V}(s^a \mu) d\mu = A_{r,\lambda} \sum_{m=1}^{M} \sum_{l=1}^{L_m} B_{m,l,r_m,\lambda} \int_0^\infty e^{-(1-sN_0)E_s} (s^a \mu)^{r_m-1} e^{-sN_0 \mu} ds \tag{33}
\]

where the last step of (33) is achieved by calculating the integral and substituting \( l \) with \( r_m - L + 1 \), and \( a \) stands for \( R_0^a \) and \( t^a \) in (32).

Therefore, by combing (7), (32) and (33), the PEP can be approximately estimated as

\[
P(X \rightarrow X) \approx \frac{2A_{r,\lambda}}{3\sqrt{3}R^2} \int_{-\infty}^{\infty} \sum_{m=1}^{M} \sum_{l=1}^{L_m} B_{m,l,r_m,\lambda} \left[ C_{s,\lambda_m,L} + D_{s,\lambda_m,L} - E_{s,\lambda_m,L} \right] \frac{ds}{\sqrt{s}}, \tag{34}
\]

where

\[
C_{s,\lambda_m,L} = \frac{R_0^{L+2}}{2 \left[ s(1-sN_0)E_s \lambda_m + R_0^L \right]^2}, \tag{35}
\]

\[
D_{s,\lambda_m,L} = \int_{R_0}^{\infty} \frac{t^{a+1}}{\left[ s(1-sN_0)E_s \lambda_m + t^a \right]^2} dt, \tag{35}
\]

\[
E_{s,\lambda_m,L} = \frac{6}{\pi} \int_{\frac{\sqrt{3}R}{2t}}^{\frac{R}{t}} t^{a+1} \arccos \left( \frac{\sqrt{3}R}{2t} \right) \frac{ds}{\sqrt{s}}, \tag{35}
\]

In the following, we investigate the diversity order for the Case II. Since \( \hat{g}_{n,k} \sim CN(0,1) \) and hence \( \hat{g}_{n,k}^2 \) are i.i.d. exponential RVs with unit mean, from (9) and (27), it holds

\[
\Phi_\Delta(s) \approx \sum_{k=1}^{K} E\left\{ \hat{g}_{n,k}^2 \right\} e^{-s(1-sN_0)E_s} \int_0^\infty \frac{1}{(1+\frac{\hat{g}_{n,k}^2}{4N_0}) N} \chi(s, N) ds \tag{36}
\]

As the distance RV satisfy 0 < \( \hat{d} \leq R \), similar as that in (16), the Chernoff bound approximation is given by

\[
P_{ch}(X \rightarrow \hat{X}) \approx \sum_{k=1}^{K} \frac{1}{(1+\frac{\hat{g}_{n,k}^2}{4N_0}) N} \chi(s, N). \tag{37}
\]

where $(\alpha)$ is from the large SNR approximation as in Case I, $G_d(\mathbf{X}, \hat{\mathbf{X}})$ is the number of nonzeros in $\lambda_1, \cdots, \lambda_K$, and

$$G_e(\mathbf{X}, \hat{\mathbf{X}}) = \prod_{k=1, \lambda_k \neq 0}^K \lambda_k \mathbb{E}_d \left[ d^\alpha G_d(\mathbf{X}, \hat{\mathbf{X}}) \right]^{-\frac{1}{N}},$$

(38)

which is a constant that is independent with SNR, denoting the coding advantage. Therefore, the system achieves the same diversity order but a different coding gain with that in Case I. Using a similar analysis as that in Case I, if the fundamental properties of the multiuser codebooks are the same, equal power allocation strategy will be a reasonable choice in terms of achieving good performance for Case II.

IV. NUMERICAL RESULTS AND SIMULATIONS

In this section, simulation results are presented to demonstrate the performance of SCMA, and also verify the effectiveness of the analysis. The considered SCMA system follows a factor graph matrix as in Table I, where 6 users multiplexing over 4 spreading chips ($J = 6, K = 4$). The performance of both joint ML and message passing algorithm (MPA) detection are investigated, and equal power allocations are assumed. The detailed simulation configurations for uncoded and coded scenarios are given in Table I. Without loss of generality, we set $R_0 = 1.2$ m all the time.

We first provides the results for Case I. Fig. 2 illustrates the diversity gains of the uncoded SCMA scheme with fading parameters $R = 3$ m, $\alpha = 2$ and 1/2/3 receive antennas. First, we can see that the analytical results of the SER analysis are very tight in the large SNR region, for all numbers of receive antennas. Second, it can be seen that a considerable performance improvement can be achieved with diversity arrays. With only two receive antennas, the system provides a huge gain that has an overall diversity order of 4, where the multidimensional codebook contributes a signal-space diversity of two. As an example for performance enhancement, we also provide the results with the proposed power allocation. It is obvious that the performance are improved and the gains become more evident for a larger number of receive antennas.

Fig. 3 shows the impact of different path-loss parameters on the performance of uncoded SCMA with two receive antennas. The result of small-scale fading environment where $\alpha = 0$ is also presented for comparison. In this configuration, the diversity order is always four, but there is a very large gap in coding gains for different path-loss environments. Both the distances between the users and the BS and the path-loss factor greatly deteriorate the SER performance, which means that considerable SNRs are required to compensate the power loss for long distance transmissions.

Fig. 4 and 5 present the uncoded results for Case II. In Fig. 4, performance of SCMA with different diversity arrays are provided for randomly distributed users. A similar observation can be observed as that in Fig. 2, a great improvement in SER performance can be achieved with receive diversity. While the theoretical performance analysis is based on the approximated union bound, the analytical bounds are still very tight for all numbers of receive antennas, which shows the effectiveness of the proposed method for SER estimation. Also, Fig. 5 investigates the impact of different path-loss on the performance. Just as expected, the large-scale path-loss preserves the diversity order while decreases the coding gain. Moreover, it is evident that the performance of the MPA detector is as good as the optimal ML detector, for all the
simulation scenarios and fading parameters.

Finally, to further verify the effectiveness of the proposed power allocations, Fig. 6 provides the simulated bit-error rate (BER) performance of a bit-interleaved half-rate turbo-coded SCMA scenario for Case I, with fading parameters $R = 3 \text{ m}, R_0 = 1.2 \text{ m}, \alpha = 2$. An iterative detection and decoding receiver [4] with 3 MPA iterations and 3 outer iterations is employed. As it is observed, a very large performance gain can be achieved with the proposed power allocation strategy. Moreover, the performance gap between the BER curves becomes larger with the proposed power allocation strategy. Moreover, the proposed power allocation strategy. Moreover, the proposed power allocation strategy. Moreover, the proposed power allocation strategy.

V. CONCLUSIONS

We have carried out in this paper the performance analysis for uplink SCMA scenarios with receiving diversity and randomly distributed users. Tight upper bounds on the SER have been developed for two situations where the distances between the users and the BS are fixed and random. For both cases, it is shown that with only a small number of receive antennas, SCMA can achieve significant SER performance gains. From both theoretical and simulation results, the study shows that a diversity order equals to the product of the number of receive antennas and the signal-space diversity can be achieved, and the large-scale path-loss reduces only the coding gain.
